Abstract

This thesis describes the search for heavy resonances decaying into top quark pairs in fully hadronic decay modes. The search uses proton-proton colliding events recorded with the ATLAS detector at the Large Hadron Collider (LHC) running at a center-of-mass energy of 13 TeV. The data corresponds to an integrated luminosity of 36.1 fb^{-1} .

A lot of new physics models beyond the Standard Model predicts heavy new particles decaying into top quark pairs. This search is a model independent search of new particles, and many kinds of new models can be tested at the same time.

The fully-hadronic final state has the highest branching ratio in the decay of top quark pairs. The resolution of reconstructed top mass and top pair mass are better than the other final-states because all the final-state particles can be reconstructed. The target mass region of new particle is in a TeV scale where yields of multijets background is relatively low. In addition, both of top quarks decaying from heavy new particle are highly boosted in the region.

The boosted top quark is reconstructed using the anti- k_T jet algorithm with a radius parameter of 1.0, referred to as large- R jets.

Top-quark jets are identified with mass of the large- R jet and τ_{32}^{wta} , which shows whether the substructure of large- R jet is three-prong like or not. The top quark jet is also required to include an associated b-tagged track jet reconstructed with the radius parameter of 0.2. multijets background is estimated using a data-driven method.

The sensitivity of this search is expected as the same as a search in the semi-leptonic final state. If no new particles are found, expected exclusion limits can reach to a mass of 3.1 TeV for the Leptophobic Z'_{TC2} at the 95% confidential level and a mass of 3.5 TeV for the Kaluza–Klein gluon.

1. Introduction

Resonance search is to look for evidence of new particles which make a statistical difference between the expected distribution and the experimental data. The expected distribution is estimated from the Standard Model (SM). If a new particle decays into two top quarks, a mass peak can be observed around the mass of new particle in the invariant mass of the $t\bar{t}$ system. This analysis looks for a significant difference in $m_{t\bar{t}}$ distribution. The search does not depend on a certain physics model, because the approach of resonance search is to simply evaluate any enhancement in the $m_{t\bar{t}}$ distributions observed in data. This feature is a strong point of this analysis, because several physics models can be judged through this analysis.

This thesis focuses on the top-antitop ($t\bar{t}$) mass spectrum. The top quark is the heaviest particle in the SM and has a very large coupling to the Higgs boson. New physics models propose an alternative Electroweak Symmetry Breaking mechanism, which predicts new particles with a larger coupling to the top quark, than to the lighter quarks.

The search reconstructs hadronically decaying $t\bar{t}$ events, where each of W bosons from top and anti-top quarks decays to two quarks. This decay topology is called as a all-hadronic channel. The channel has a large statistics, which is suitable for the search. However the large contamination of the multijet events makes the reconstruction of the events challenging. The reconstruction of top quarks is performed large size jets, namely anti- k_T jets with the radius parameter $R=1.0$. In the high mass region of the $t\bar{t}$ system, top and anti-top quarks are highly boosted and their decay products are expected to be collimated. As a result, a top quark can be reconstructed as a large- R jet. This allows to access high p_T top quarks with a reasonable resolution.

Previous searches performed by the ATLAS, CMS, CDF and DØ collaborations [1–4] have set limits on this resonance. In case of the Z' search, the most stringent mass limit has been set as $m_{Z'} > 2.1$ TeV [1, 3, 5–14].

In this thesis, the search is performed using the proton-proton colliding events recorded with the ATLAS detector at the Large Hadron Collider (LHC) running at a center-of-mass energy of 13 TeV. The data corresponds to an integrated luminosity of 36.1 fb^{-1} .

The outline of this thesis is as follows.

Chapter 2 states the strategy of the resonance search and theoretical background of this analysis.

Chapter 3 shows a brief summary of the LHC and the ATLAS detector.

Monte-Carlo simulation samples are summarized in Chapter 4.

Chapter 5 provides the definition of objects which are used in the event selection of this analysis.

From Chapter 6 to 9, the details for main part of this analysis are described.

How to optimize the signal event selections is written in Chapter 6

In Chapter 7, the result of checking the contributions of every possible background is shown, and the details of multi-jet estimation with data driven method is provided.

Chapter 8 summarizes the systematic uncertainties in this analysis.

Expected cross section limits for several signal models are provided as a result in Chapter 9.

Chapter 10 gives the conclusions of this thesis.

In this thesis, a resonance search is performed using a $t\bar{t}$ invariant mass spectrum.

2. Theoretical background

The Standard Model (SM) of particle physics can explain the most of the fundamental physics phenomena. However the SM still gives remained some problems. In order to solve those problems, the new physics beyond the SM (BSM) are needed, and many kinds of the BSM models have been proposed.

In this chapter, the SM is introduced, and those problems of the SM are summarized. Some theories of the BSM which can be searched in this analysis are also introduced.

2.1. The Standard Model

On 2012, the Higgs boson which was the last piece of the SM was discovered, and all elementary particles predicted in the SM are found [15]. There are two types of elementary particles. One of them is called fermions which obeys the Fermi-Dirac statistics, while the other is called bosons obeying the Bose-Einstein statistics. Fermions and bosons are summarized in Table 1 and 2, respectively.

Table 1: Fermions in the SM. The quantum numbers Q , I , I^3 , Y are electrical charge, weak isospin, third components of weak isospin, and weak hyper charge, respectively. L and R denote left- and right-handed chiral states, respectively.

	Generation			Quantum Number			
	1st	2nd	3rd	Q	I	I^3	Y
Quarks	$\begin{pmatrix} u \\ d \end{pmatrix}_L$ u_R d_R	$\begin{pmatrix} c \\ s \end{pmatrix}_L$ c_R s_R	$\begin{pmatrix} t \\ b \end{pmatrix}_L$ t_R b_R	$\begin{pmatrix} 2/3 \\ -1/3 \end{pmatrix}$ $2/3$ $-1/3$	$1/2$ 0 0	$\begin{pmatrix} 1/2 \\ -1/2 \end{pmatrix}$ 0 0	$1/3$ $4/3$ $-2/3$
Leptons	$\begin{pmatrix} \nu_e \\ e^- \end{pmatrix}_L$ e_R^-	$\begin{pmatrix} \nu_\mu \\ \mu^- \end{pmatrix}_L$ μ_R^-	$\begin{pmatrix} \nu_\tau \\ \tau^- \end{pmatrix}_L$ τ_R^-	$\begin{pmatrix} 0 \\ -1 \\ -1 \end{pmatrix}$	$1/2$ 0	$\begin{pmatrix} 1/2 \\ -1/2 \end{pmatrix}$ 0	-1 -2

Table 2: Bosons in the SM. The quantum numbers S^P , Q , I , I^3 , Y are spin-parity,electrical charge, weak isospin, third components of weak isospin, and weak hyper charge, respectively. The values of mass are taken from [16].

		mass[GeV/ c^2]	S^P	Q	I	I^3	Y	Interaction
Weak bosons	Photon	γ	0	1^-	0	0	0	electromagnetic
	W^\pm	80.385	1^-	± 1	1	± 1	0	
	Z	91.1876	1^-	0	0	0	0	weak
Gluon	g	0	1^-	0	0	0	0	strong
Higgs	h	125.7	0^+	0	$1/2$	$-1/2$	1	

The SM provides unified description of fundamental interaction in the nature. The fermions are quarks and leptons, and form a matter. Quarks have up-type and down-type, and then both quarks and leptons are separated by the three categories called generation (1st, 2nd and 3rd). In addition, there are anti-fermions which has the same mass for fermions but has the opposite values for the other properties. The bosons are consist of four gauge bosons and the Higgs boson. Photon, weak bosons and gluon mediate electromagnetic interaction, weak interaction (See Sec. 2.1.3) and strong interaction (See Sec. 2.1.2), respectively. The Higgs boson interacts to all particles by the Yukawa interaction and the particles obtain

own masses by this interaction through the Brout-Englert-Higgs mechanism (BEH mechanism) [17] (See Sec. 2.1.4).

2.1.1. Quantum electrodynamics (QED)

In 1865, electricity and magnetism were unified into a single theory as the electromagnetic theory by Clerk Maxwell. Later, the electromagnetic theory was quantized by Dirac, and the quantum-electromagnetic dynamics (QED) was completed by Tomonaga, Schwinger and Feynman [18–21].

The Lagrangian of an electron in a field-free space can be written as

$$\mathcal{L}_{\text{Dirac}} = \bar{\Psi} (i\gamma^\mu \partial_\mu - m)\Psi, \quad (1)$$

where Ψ denotes the electromagnetic fields, γ^μ ($\mu = 0, 1, 2, 3$) satisfy

$$\gamma^0 = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad \gamma^i = \begin{bmatrix} 0 & \sigma_i \\ -\sigma_i & 0 \end{bmatrix}, \quad (2)$$

where σ_i ($i = 1, 2, 3$) denote Pauli matrix. If local phase transformation ($U(1)$ transformation)

$$\Psi \rightarrow e^{-ie\theta}\Psi$$

is performed, the $\mathcal{L}_{\text{Dirac}}$ has local gauge invariance with the following covariant derivative :

$$D_\mu = \partial_\mu + ieA_\mu, \quad (3)$$

where A_μ denote a vector field (photon field). The $\mathcal{L}_{\text{Dirac}}$ is changed as

$$\begin{aligned} \mathcal{L}_{\text{Dirac}} &= \bar{\Psi} (i\gamma^\mu D_\mu - m)\Psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} \\ &= \bar{\Psi} (i\gamma^\mu \partial_\mu - m)\Psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} - e(\bar{\Psi}\gamma^\mu\Psi)A_\mu, \end{aligned} \quad (4)$$

where $F_{\mu\nu}$ is field-strength and satisfy

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu. \quad (5)$$

The first term of Eq.4 shows the electron kinetic term and the electron mass term. The second term is the photon kinetic term, and the third term denotes an interaction between electromagnetic current and photon field (electromagnetic interaction). It is important to obtain the interaction term through the local gauge transformation, and it means that the form of an interaction is decided by introducing a gauge field.

If the $U(1)$ transform is generalized by Lie-group, the transformation can be denoted as

$$G(\epsilon) = e^{i\epsilon^a T^a}, \quad (6)$$

where ϵ denotes a parameter, and T is a generator of the Lie-group. T satisfy

$$[T^a, T^b] = if^{abc}T^c, \quad (7)$$

where f denotes a structure constant of the Lie-group. When the gauge transformation can be written as

$$\Psi_i(x) \rightarrow [G(g\epsilon(x))]_{ij}\Psi_j(x) = [e^{ig\epsilon^a(x)T^a}]_{ij}\Psi_j(x), \quad (8)$$

Eq. (5) can be written as

$$F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + g f^{abc} A_\mu^b A_\nu^c. \quad (9)$$

g denotes the gauge coupling constant.

2.1.2. Quantum chromodynamics (QCD)

The color quantum number of quark is known as 3 by the observation of π_0 decay and the measurement of cross-section ratio $\sigma(e^+e^- \rightarrow \text{hadrons})/\sigma(e^+e^- \rightarrow \mu^+\mu^-)$ [22]. Quark dynamics can be understood using a non-abelian gauge theory with the symmetry group of the $SU(3)$. The Lagrangian of QCD can be written as

$$\begin{aligned} \mathcal{L}_{\text{QCD}} &= \bar{q}(i\gamma^\mu D_\mu)q - \frac{1}{2}Tr G_{\mu\nu} G^{\mu\nu} \\ &= \bar{q}(i\gamma^\mu \partial_\mu)q - g_s(\bar{q}\gamma^\mu T_a q)G_\mu^a - \frac{1}{2}Tr G_{\mu\nu} G^{\mu\nu}, \end{aligned} \quad (10)$$

where q denotes the color-triplet quark fields, G denotes gluon fields and D_μ is chosen as

$$D_\mu = \partial_\mu + ig_s G_\mu. \quad (11)$$

G_μ satisfies the followings

$$G_\mu = T_a G_\mu^a \quad (12)$$

$$G_{\mu\nu} G^{\mu\nu} = \partial_\mu G_\nu - \partial_\nu G_\mu + ig_s[G_\mu, G_\nu]. \quad (13)$$

g_s is the strong coupling constant. The coupling constant can be written as

$$\alpha_s = \frac{g_s^2}{4\pi}, \quad (14)$$

where scale dependence of α_s can be described by

$$\alpha_s(Q) = \frac{4\pi\alpha_s(\mu_R)}{4\pi + \beta_0\alpha_s(\mu_R \ln(Q^2/\Lambda_{\text{QCD}}^2))}, \quad (15)$$

where μ_R denotes the renormalization scale, Λ_{QCD} is the cut-off scale and β_0 denotes a constant computed from a beta function for QCD [23–27], it can be negative, therefore the strong interaction decreases logarithmically as a function of Q . As a result, a behavior of the strong interaction is quite local (the behavior is well known as asymptotic freedom). Quarks and gluons can not be isolated because of the color confinement. At high energy interactions, a generated quark interacts with other quarks and antiquarks generated in the vacuum, and then they form a lot of hadrons. The hadrons are observed in the direction of the motion of the original quark, and resulting in a collimated spray of hadrons. It is

called as jet, and the phenomena is called as hadronization. The time scale of hadronization is equal to $1/\Lambda_{\text{QCD}} \sim 10^{-24}$ s. The life time of quarks except for top quarks are longer than the hadronization time-scale, while the life time of top quark is about 10^{-25} s. Therefore, top quarks are not hadronized, and it can not form mesons.

2.1.3. Electroweak theory

The electroweak theory achieved to combine QED and electroweak interaction [28–30]. Each fermion has weak isospin (I, I^3) and weak hyper charge Y as seen in Table 1. From an analogy to QED, weak interaction is occurred by exchanging the charge via weak fields. There are four fields and four massless bosons for each charge (Q, I, I^3 and Y). A gauge symmetry $SU(2)_L \times U(1)_Y$ is introduced. The iso-triplet ($SU(2)$) has three bosons $\mathbf{W}_\mu = (W_\mu^1, W_\mu^2, W_\mu^3)$, and the iso-singlet ($U(1)_Y$) has B_μ .

The Lagrangian of the electroweak interaction can be written as

$$\mathcal{L}_{\text{EW}} = \bar{\psi}(i\gamma^\mu D_\mu - m)\psi - \frac{1}{4}\mathbf{W}_{\mu\nu}\mathbf{W}^{\mu\nu} - \frac{1}{4}B_{\mu\nu}B^{\mu\nu}, \quad (16)$$

where $\mathbf{W}_{\mu\nu}$ is defined as

$$\mathbf{W}_{\mu\nu} = \partial_\mu \mathbf{W}_\nu - \partial_\nu \mathbf{W}_\mu - g \mathbf{W}_\mu \times \mathbf{W}_\nu, \quad (17)$$

$B_{\mu\nu}$ is also defined as

$$B_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu. \quad (18)$$

D_μ is set as

$$D_\mu = \partial_\mu + ig \sum_{a=1}^3 \mathbf{W}_\mu^a \tau_a + ig' \frac{Y}{2} B_\mu, \quad (19)$$

where g and g' denote the coupling constant of $SU(2)_L$ and $U(1)_Y$, respectively, and τ is given by

$$\tau = \frac{1}{2}(\sigma_1, \sigma_2, \sigma_3). \quad (20)$$

Using the covariant derivative Eq. (19), the Lagrangian of electroweak(Eq. 16) can be written as

$$\mathcal{L}_{\text{EW}} = i\bar{\psi}\gamma^\mu \partial_\mu \psi - g'\bar{\psi}\gamma^\mu \frac{Y}{2} B_\mu \psi - \frac{1}{4}\mathbf{W}_{\mu\nu}\mathbf{W}^{\mu\nu} - \frac{1}{4}B_{\mu\nu}B^{\mu\nu} - \frac{g}{2}\bar{\psi}_L \gamma^\mu \begin{bmatrix} W_\mu^3 & (W_\mu^1 - iW_\mu^2) \\ (W_\mu^1 + iW_\mu^2) & -W_\mu^3 \end{bmatrix} \psi_L. \quad (21)$$

2.1.4. Spontaneous symmetry braking and the Brout-Englert-Higgs mechanism

As seen in Eq. (21), the Lagrangian do not have a mass term. It means that the bosons and all fermions do not have mass. However we know fermions are massive and massive bosons have been discovered. Therefore, a mechanism which naturally gives mass to those fundamental particles is needed, and the Brout-Englert-Higgs mechanism (the BEH mechanism) has achieved success to solve this problem. In

the BEH mechanism, scalar fields $\phi = (\phi^+, \phi^0)$ and $SU(2)$ doublet are introduced. ϕ^+ has weak isospin +1/2 and weak hyper charge +1/2, and ϕ^0 has weak isospin -1/2 and weak hyper charge +1/2.

The Lagrangian of the higgs field can be written as

$$\mathcal{L}_{\text{higgs}} = (D_\mu \phi)^\dagger (D^\mu \phi) - V(\phi), \quad (22)$$

where $V(\phi)$ denotes the higgs potential and satisfies

$$\begin{aligned} V(\phi) &= \mu^2 |\phi|^2 + \lambda |\phi|^4 \\ &= \lambda (|\phi|^2 - \frac{v^2}{2})^2 (if \mu^2 < 0). \end{aligned} \quad (23)$$

The potential is always minimum at $\phi = (0, 0)$, if $\mu^2 > 0$. However the potential is minimum at $|\phi|^2 = -\mu^2/2\lambda$, if μ^2 has a negative value. Hence the vacuum has an expected value, which it is called the vacuum expectation value and denoted by v . This means that the phase transition of vacuum can be occurred for μ^2 , and the vacuum obtains a freedom on the $\phi^+ - \phi^0$ plane associated with $\phi = (0, v)$. The phase transition of vacuum is called spontaneous symmetry braking, and the vacuum can be redefined as

$$\phi = \begin{pmatrix} 0 \\ v + h(x) \end{pmatrix}. \quad (24)$$

$\partial_\mu \rightarrow D_\mu$ is applied in Eq. (19), the mass terms of gauge bosons are generated. As a result, W and Z bosons obtain mass as

$$m_W = \frac{gv}{2}, \quad (25)$$

$$m_Z = \frac{v\sqrt{g^2 + g'^2}}{2}. \quad (26)$$

The higgs mass is

$$m_{\text{higgs}} = \sqrt{-2\mu^2}. \quad (27)$$

Fermions also obtains mass, and this interaction is known as Yukawa interaction. The Lagrangian of Yukawa interaction can be written as

$$\mathcal{L}_{\text{Yukawa}} = -\bar{\psi}_{i,L} y_{ij}^a \phi \psi_{j,R} - \bar{\psi}_{i,R} y_{ij}^a \phi^\dagger \psi_{j,L}. \quad (28)$$

2.2. Problem of the Standard Model

The SM achieves to unify the electromagnetic theory and the weak theory, and the QCD theory in the SM can explain the strong interaction. However the gravitational interaction is not included in the SM,

and some problems have remained. One of the problems is the fine-tuning problem, and another is the existence of Dark Matter.

2.2.1. The fine-tuning problem

The physical Higgs mass is defined by

$$m_h^2 = 2 m_{h,\text{bare}}^2 + \delta m_h^2 \quad (29)$$

where $m_{h,\text{bare}}$ denotes the bare Higgs mass and δm_h^2 is the quadratically divergent radiative correction given by

$$\delta m_h^2 = \frac{3|\lambda|^2}{8\pi^2} \Lambda^2 + O(\log\Lambda) \quad (30)$$

where Λ denotes the cut off scale which is the effective limit of the SM and λ denote the Yukawa coupling constant. If the effective limit of the SM is at the Plank scale ($O(10^{19}$ GeV)), the radiative correction can be $O(10^{38}$ GeV). The physical Higgs mass is observed as 125 GeV. Therefore, $m_{h,\text{bare}}$ and δm_h^2 should be canceled with a precision of $O(10^{-17})$. This unnatural treatment is called the fine-tuning problem.

2.2.2. Dark Matter

The existence of Dark Matter (DM) is predicted from the observation of the rotation of a galaxy by Rubin and Ford [31, 32] for the first time by Rubin and Ford [31, 32]. Later, the spatial distribution of DM is estimated, and a 3-dimensional map of DM in the universe is created by measuring the effect of the gravitational lens [33]. However there is no candidate of DM in the SM. Therefore the existence of a new particle is needed.

2.3. Candidates of a new particle detectable in the $t\bar{t}$ resonance search

Candidates of a new particle which can be found in the $t\bar{t}$ resonance search are introduced in this section.

2.3.1. Leptophobic top-color Z'

The first candidate is a spin-1 color-singlet vector boson, denoted Z'_{TC2} , predicted in the topcolour-assisted technicolor model based on the extended technicolor model [34–36]. This model assumes the existence of additional strong dynamics and a new gauge boson at TeV scale.

This boson couples strongly to first and third generation quarks, and does not decay to leptons. The tendency is referred to as Model IV in [35]. In this model, Z'_{TC2} is produced by quark-antiquark annihilation.

2.3.2. Bulk Randall–Sundrum Kaluza–Klein Graviton

The second candidate is a spin-2 bulk Randall–Sundrum Kaluza–Klein graviton, denoted RS- G_{KK} , predicted in the Randall–Sundrum models [37]. The model assumes the existence of an extra dimension. Our dimension is defined as a weak brane and an additional brane is defined as gravity brane. In this model, the vacuum expectation value V_{eff} is given by

$$V_{\text{eff}} = e^{-kL} V \quad (31)$$

where $k = \sqrt{\frac{-\Lambda}{12M^3}}$, and it is related to an oscillating warp factor. L denotes the distance between the two branes. Even if the bare Higgs mass is at the order of the Plank scale, the physical Higgs mass on the weak brane could be wrapped down to the weak scale without the fine tuning.

2.3.3. Kaluza–Klein gluon

The third candidate is a spin-1 Kaluza–Klein(KK) gluon predicted by the Kaluza Klein theories [38, 39]. Those theories assume the existence of warped extra-dimensions. In particular, the Randall-Sundrum (RS) model [40] of KK theories assumes the existence one extra dimension, and predicts the existence of gluon excitations with strong coupling with quarks $g_f \approx 0.2g_s$, and stronger coupling with a top quark. The RS-model predicts chiral coupling with the top quark: $g_R^{(t)} \approx 4g_s$ and $g_L^{(t)} \approx 1g_s$ [41]. The KK-gluon is produced in $p-p$ collisions mostly from a $q\bar{q}$ initial state. The tree-level gluon-gluon-KKgluon interaction is calculated to be exactly zero in the Randall-Sundrum model [42], and 1-loop (anomalous) production ('a la Higgs) is forbidden at the first order by Yang's theorem where spin-1 particles do not decay into two massless vectors. At a higher order, the gluon-initiated cross section is calculated to be 10^{-3} to 10^{-4} of the quark-initiated cross section [42].

Those lightest KK particles can be the candidate of the DM.

3. LHC and the ATLAS experiment

3.1. Large Hadron Collider

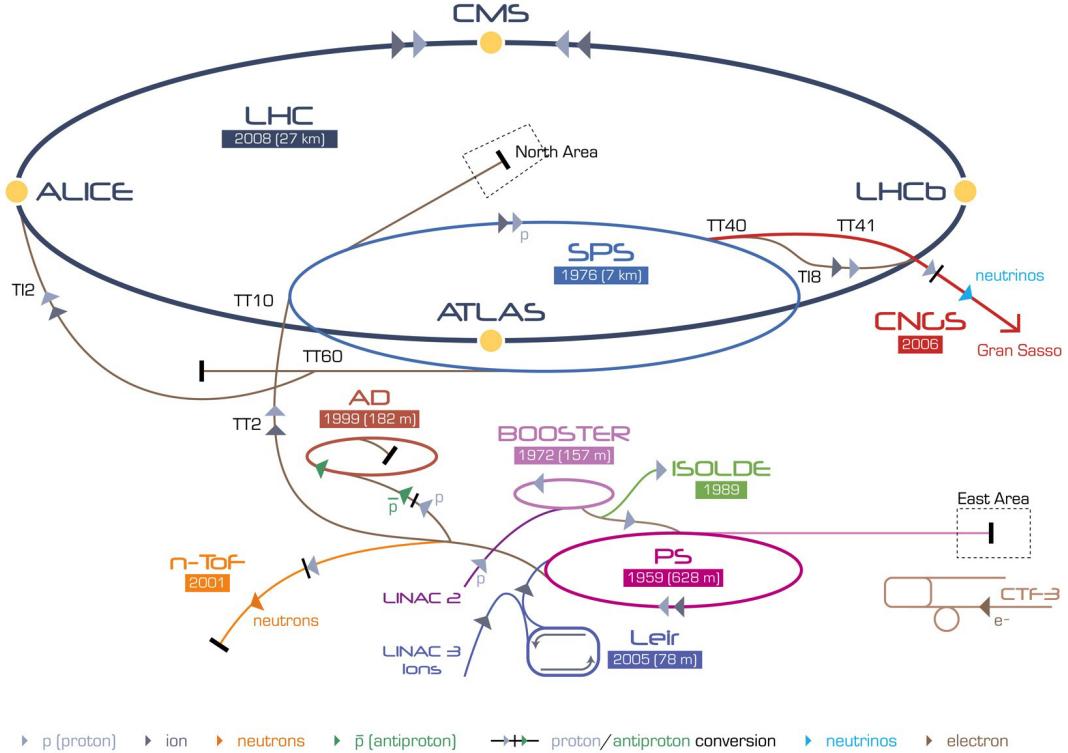

Figure 1: The LHC and the other facilities [43]

The Large Hadron Collider (LHC) is the largest proton-proton circular collider (length: 26.7 km) at CERN. The accelerator complex at CERN for accelerating proton beam is schematically illustrated in Fig. 1. The proton beams are produced at the positive ion source and accelerated at the Linac 2. The beam energy reaches 50 MeV. The beams are further accelerated to 1.4 GeV at the Proton Synchrotron Booster (PSB), and to 2.5 GeV in the Proton Synchrotron (PS). The beams are then injected to the Super Proton Synchrotron (SPS), and accelerated up to 450 GeV, to be instead to the LHC. Here, beams circulate opposite directions are injected. Finally the beams are accelerated to 6.5 TeV in the LHC.

3.2. ATLAS

ATLAS (A Toroidal LHC Apparatus) detector [44] is placed at CERN. It covers nearly the entire solid angle around a collision point. It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer incorporating three large superconducting toroid magnets (Fig. 2).

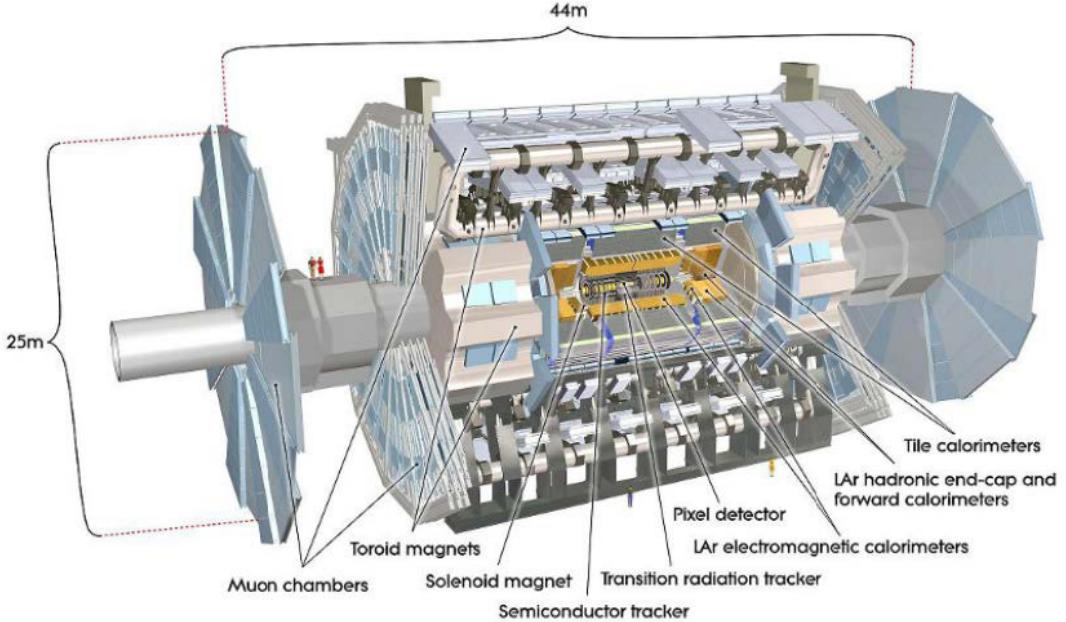

Figure 2: The ATLAS detector overview [45]. The height, length and weight are 25 m, 44 m and 7000 t, respectively

3.2.1. Coordinate system in the ATLAS experiment

The ATLAS coordination system uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the ATLAS detector and the z -axis along the beam pipe. The x -axis points from the IP to the centre of the LHC ring, and the y -axis points upwards. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the z -axis. The pseudo-rapidity is defined in terms of the polar angle θ as written in the Eq. (32).

$$\eta = -\ln \tan(\theta/2), \quad (32)$$

Covered regions are separated to three regions as Barrel, End-cap and Fore-ward by the pseudo-rapidity, respectively $|\eta| < 1.05, 1.05 < |\eta| < 2.4, 2.4 < |\eta|$.

Angular distance is measured in units of ΔR defined as the Eq. (33).

$$\Delta R \equiv \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} \quad (33)$$

3.2.2. Inner Detector

The inner-detector system (ID) is immersed in a 2 T axial magnetic field and provides charged particle tracking in the range $|\eta| < 2.5$. The system overview is showed in Fig. 3.

The high-granularity silicon pixel detector covers the vertex region and typically provides three measurements per track, the first hit being normally in the innermost layer. The total number of channels are about

80 million, and the detector resolutions are $12 \mu\text{m}$ for the direction of r and ϕ , $70 \mu\text{m}$ for the direction of z axis.

It is followed by the silicon micro-strip tracker which usually provides four two-dimensional measurement points per track. These silicon detectors are complemented by the transition radiation tracker (TRT), which enables radially extended track reconstruction up to $|\eta| = 2.0$. The transition radiation tracker also provides electron identification information based on the fraction of hits (typically 30 in total) above a higher energy deposit threshold corresponding to transition radiation. The total number of channels are about 300000, and the detector resolutions are $170 \mu\text{m}$.

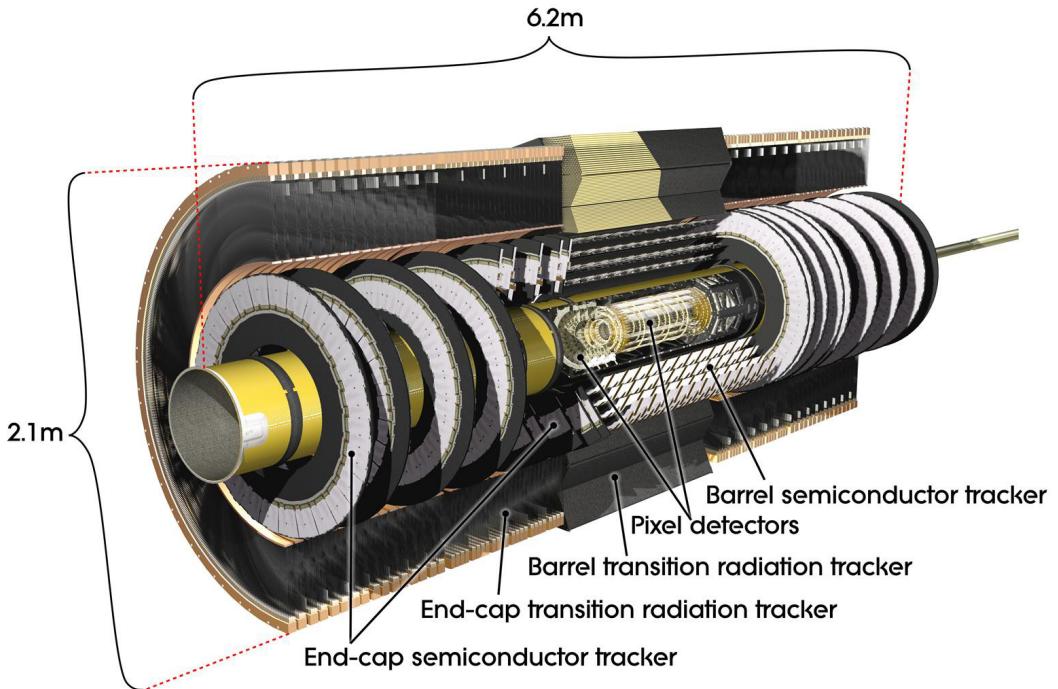

Figure 3: Inner Detector overview [46]

The detector system is the most important for the bottom quark identification.

3.2.3. Calorimeter

The calorimeter system covers the pseudo-rapidity range $|\eta| < 4.9$. The overview is in Fig. 4. Within the region $|\eta| < 3.2$, electromagnetic calorimetry is provided by barrel and end-cap high-granularity lead/liquid-argon (LAr) electromagnetic calorimeters, with an additional thin LAr pre-sampler covering $|\eta| < 1.8$, to correct for energy loss in material upstream of the calorimeters. The electromagnetic calorimeter is mainly used by detection and separation of electron and photon. The resolution of energy is given in the Eq. (34).

$$\sigma = \frac{10\%}{\sqrt{E_\gamma [\text{GeV}]}} \quad (34)$$

$\sqrt{E_\gamma}$ denote the energy of photon. The resolutions are $9/\sqrt{E_\gamma} \text{ mm}$ for the direction of ϕ and 3 mm for the direction of the η .

Hadronic calorimetry is provided by the steel/scintillating-tile calorimeter, segmented into three barrel structures within $|\eta| < 1.7$, and two copper/LAr hadronic end-cap calorimeters. The solid angle coverage is completed with forward copper/LAr and tungsten/LAr calorimeter modules optimized for electromagnetic and hadronic measurements respectively. Boosted top quark is tagged as large- R jet, the large- R jet object

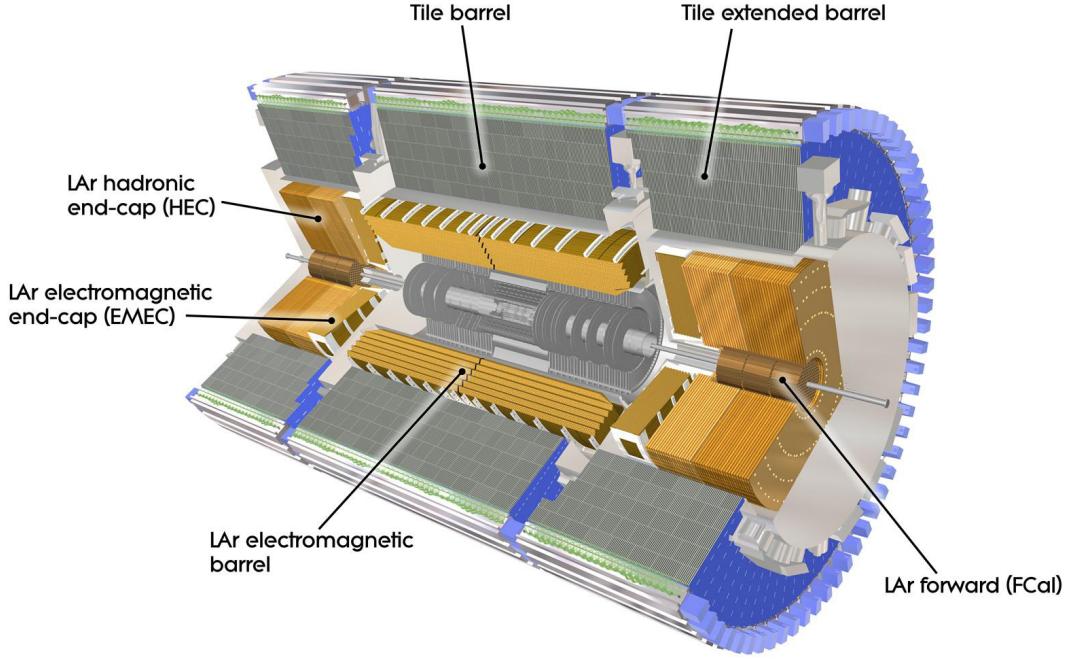

Figure 4: Calorimeter overview [46]

is reconstructed and calibrated with the information measured in the calorimeter system.

3.2.4. Muon Spectrometer

The muon spectrometer (MS) comprises separate trigger and high-precision tracking chambers measuring the deflection of muons in a magnetic field generated by superconducting air-core toroids. The precision chamber system covers the region $|\eta| < 2.7$ with three layers of monitored drift tubes, complemented by cathode strip chambers in the forward region, where the background is highest. The muon trigger system covers the range $|\eta| < 2.4$ with resistive plate chambers in the barrel, and thin gap chambers in the end-cap regions.

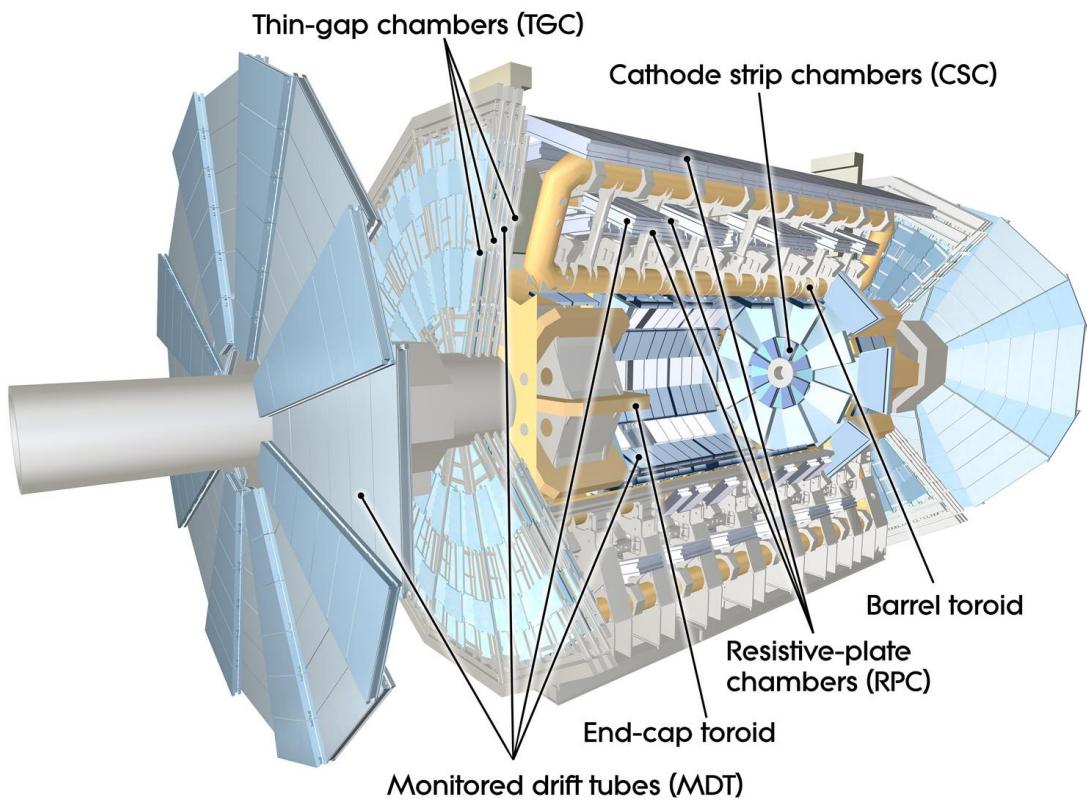

Figure 5: Muon Spectrometer overview [46]

3.2.5. Magnetic System

The ATLAS magnetic system is made of three large air-core toroid superconducting magnets with eight coils each as the Fig. 6. Its bending power is in the range from 2.0 to 7.5 T m.

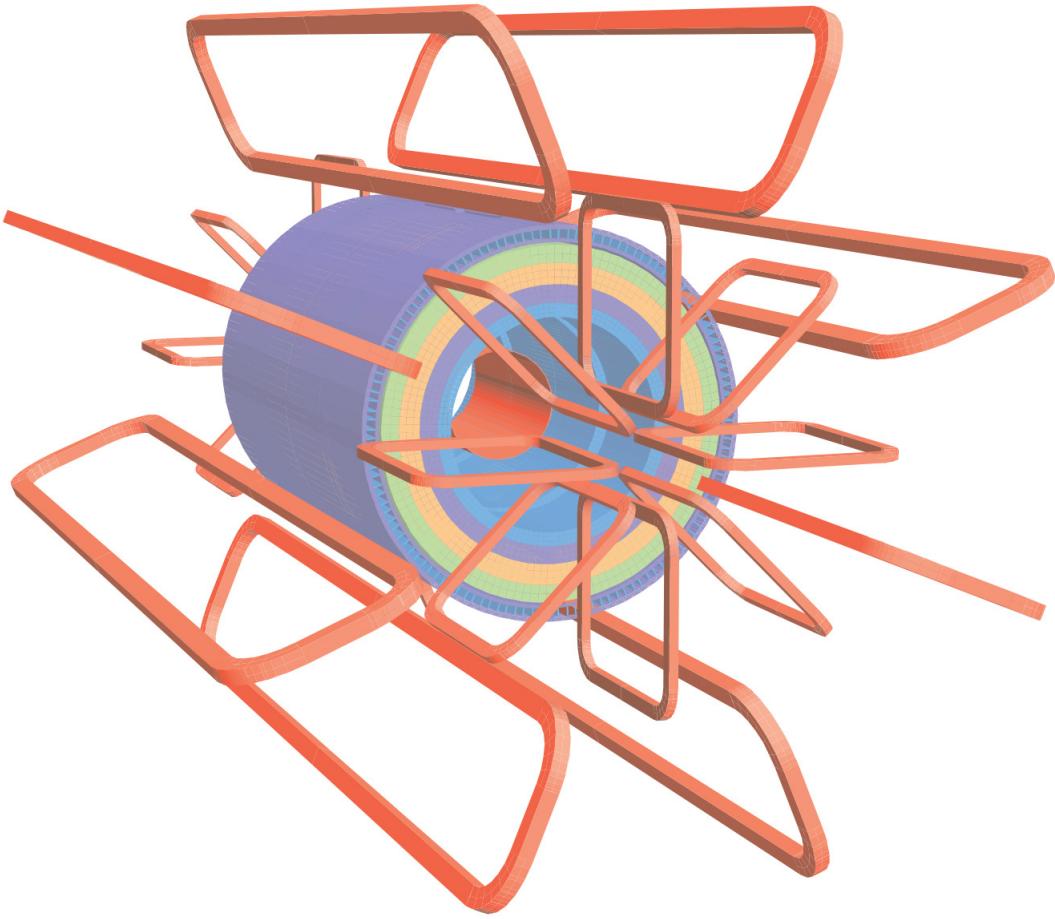

Figure 6: Sketch of the magnet system of ATLAS [46]. The eight barrel toroid and the solenoid magnet are shown, and the tile calorimeter is also shown.

3.2.6. Trigger System

A trigger system is used to select interesting physics events [47].

The Level-1 trigger is implemented in hardware and uses a subset of detector information to reduce the event rate to a design value of at most 100 kHz. This is followed by a software-based High Level Trigger (HLT) which reduce the event rate to about 1 kHz. Several trigger conditions are prepared in order to manage a wide variety of analyses.

4. Monte-Carlo simulation

The signal and background simulation samples were produced with Monte Carlo (MC) generators. The main backgrounds for this analysis are the Standard Model $t\bar{t}$ production and QCD multi-jet production.

The EvtGEN v1.2.0 program [48] is used in all simulated samples to model the properties of heavy-flavor hadron decays. All simulated samples include the effects of multiple pp interactions in the same and neighbouring bunch crossings (pile-up) and are processed through the ATLAS detector simulation [49] based on GEANT4 [50]. Pile-up effects are emulated by overlaying simulated minimum-bias events from PYTHIA 8.186 [51], generated with the MSTW2008LO PDF set [52] and the A2 tune [53] for the underlying event. The number of overlaid minimum-bias events is adjusted to match the luminosity profile of the recorded data. All the simulated samples are reconstructed with the same software as that used for collision data.

4.1. Signal samples

Although the analysis is done in a very generic way, the benchmark signal models are used to get the final results and consequently to set limits on their production rates. The benth mark signal models are prepared with respect to each spin.

4.1.1. $Z'_{TC2} \rightarrow t\bar{t}$ signal

The spin-1 color-singlet vector Z'_{TC2} bosons decaying to $t\bar{t}$ are generated with PYTHIA v8.165 with the leading-order (LO) NNPDF2.3 [54] PDF set and the A14 set of tuned parameters [55]. To account for higher-order contributions, the LO calculation of the cross section is multiplied by a factor 1.3 obtained at next-to-leading order (NLO) in QCD [56] using the PDF4LHC2015 PDF set [54].

Parameters of the model (Sec. 2.3.1) are tuned such that the resonance has a width of 1.2% of its mass. The next-to-leading-order calculation is taken into account by multiplying its cross section by 1.3, based on the calculations performed in [57, 58]. The cross-sections of Z'_{TC2} production at $\sqrt{s} = 13\text{TeV}$ calculated at leading-order (LO) are presented in the Table 3. Following [36] and the previous searches for $t\bar{t}$ resonances, a multiplicative K -factor of 1.3 is used to bring them at next-to-leading order (NLO). The benchmark model has a width of 1.2% or 3% of the mass.

Table 3: Leading-order theoretical cross-sections for the Z'_{TC2} signal extracted from LO MCs, on top of which a K -factor of 1.3 is applied.

Z' mass	LO cross-section [pb]
400 GeV	70.3
500 GeV	40.1
750 GeV	10.7
1 TeV	3.70
1.25 TeV	1.51
1.5 TeV	0.684
1.75 TeV	0.334
2. TeV	0.172
2.25 TeV	0.0924
2.5 TeV	0.0511
2.75 TeV	0.0289
3 TeV	0.0167
4 TeV	0.00213
5 TeV	0.000331

Figure 7 shows the truth $m_{t\bar{t}}$ distributions in MC for each Z'_{TC2} mass.

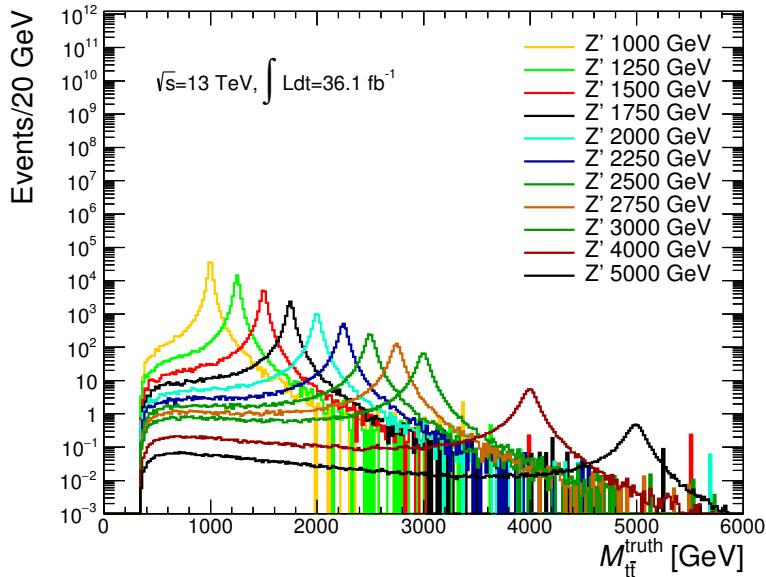

Figure 7: Distributing of $m_{t\bar{t}}$ for the generated Z'_{TC2} signals. Those distributions are scaled to 36.1 fb^{-1} of data

4.1.2. $G_{KK} \rightarrow t\bar{t}$ signal

The production of a spin-2 Bulk RS graviton with a curvature $C = k/\bar{M}_P = 1$ is performed using `MadGraph5_aMC@NLO` [59] with the LO NNPDF2.3 [60] PDF set, interfaced with `PYTHIA v8.165` with the A14 set of tuned parameters for parton shower and hadronization.

Table 4: Leading order cross-section times branching ratio, $\sigma_{G_{KK}} \times BR(G_{KK} \rightarrow t\bar{t})$, for RS graviton.

G_{KK} mass	$\sigma_{G_{KK}} \times BR(G_{KK} \rightarrow t\bar{t})$ [pb]
400	7.19
500	5.84
750	1.18
1000	2.89E-01
2000	4.98E-03
3000	2.48E-04

This spin-2 benchmark model also assumes a narrow resonance (width varied between 3 and 6% of the mass).

The cross-section times branching ratio $\sigma_{G_{KK}} \times BR(G_{KK} \rightarrow t\bar{t})$ predicted by **MADGRAPH 5**, are shown in Table 4 and are much smaller than those of the Z'_{TC2} production.

Figure 8 shows the truth $m_{t\bar{t}}$ distributions for each *RS*-graviton signal in the generated samples.

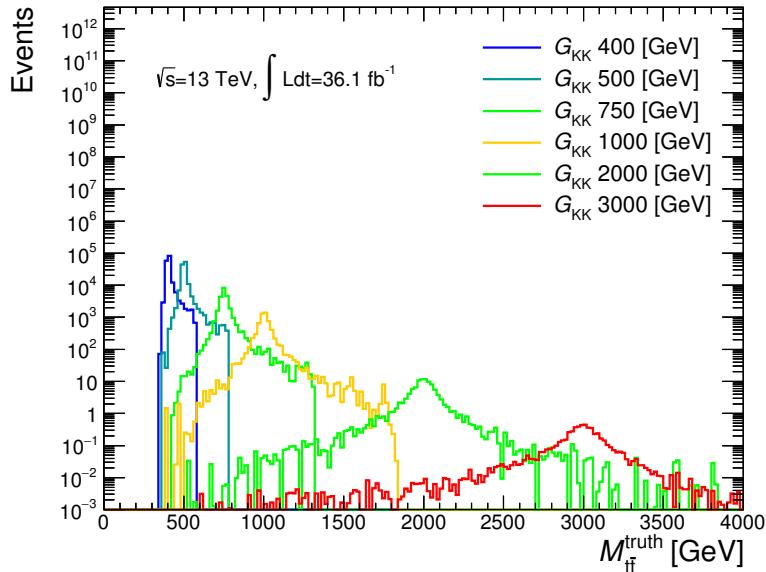

Figure 8: Distributing of $m_{t\bar{t}}$ for the truth-level *RS*-graviton signals. Those distributions are scaled to 36.1 fb^{-1} of data

4.1.3. $g_{KK} \rightarrow t\bar{t}$ signal

Simulated samples of spin-1 color-octet KK gluon g_{KK} with a width of 15% are generated with **PYTHIA** v8.165 with the same PDF and tuned parameters as those used for the Z' samples. Samples of g_{KK} with 30% width are derived from reweighting the corresponding samples with 15% width and adjusting their normalization according to the prediction for the g_{KK} with 30% width.

Table 5: Leading order cross-section times branching ratio, $\sigma_{g_{KK}} \times BR(g_{KK} \rightarrow t\bar{t})$, for KK gluon.

g_{KK} mass	$\sigma_{g_{KK}} \times BR(g_{KK} \rightarrow t\bar{t})$ [pb]
500	240.86
1000	20.176
1500	3.79
2000	1.052
2500	0.37339
3000	0.15607
3500	0.074283
4000	0.039494
4500	0.022862
5000	0.014241

The cross-section times branching ratio $\sigma_{g_{KK}} \times BR(g_{KK} \rightarrow t\bar{t})$ predicted by PYTHIA v8.165, are shown in Table 5.

Figure 9 shows the truth $m_{t\bar{t}}$ distributions for each KK gluon signal sample.

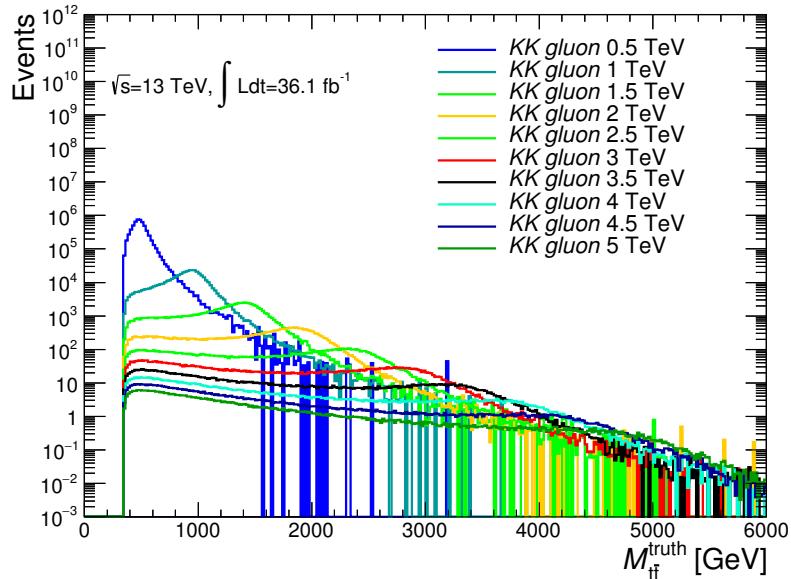

Figure 9: Distributing of $m_{t\bar{t}}$ for the truth-level KK gluon signals. Those distributions are scaled to 36.1 fb^{-1} of data

4.2. Standard Model $t\bar{t}$

The $t\bar{t}$ contribution and the modeling uncertainties are evaluated using MC simulated events.

For the generation of SM $t\bar{t}$ events, the POWHEG-Box v2 [61–63] is used with the CT10 [64, 65] parton distribution function (PDF) set in the matrix element calculations. The $t\bar{t}$ production cross section in pp collisions at $\sqrt{s} = 13 \text{ TeV}$ is $\sigma_{t\bar{t}} = 832^{+46}_{-52} \text{ pb}$ for a top-quark mass of 172.5 GeV. It has been

calculated at next-to-next-to leading order (NNLO) in QCD including resummation of next-to-next-to-leading logarithmic soft gluon terms with Top++2.0 [66–72]. Parton showering, hadronization and the underlying event are simulated using PYTHIA v6.428 [73] with the CTEQ6L1 [74] PDF set and the corresponding Perugia 2012 set of tuned parameters [75]. The h_{damp} parameter, which controls the transverse momentum of the first additional emission beyond the Born configuration, is set equal to the top-quark mass. The main effect of this parameter is to regulate the high- p_T emission against which the $t\bar{t}$ system recoils.

Figure 10 shows the truth-level $m_{t\bar{t}}$ distribution obtained in the generated $t\bar{t}$ samples. The samples are properly added according to their cross sections. Each $t\bar{t}$ samples correspond to samples with different $m_{t\bar{t}}$ thresholds.

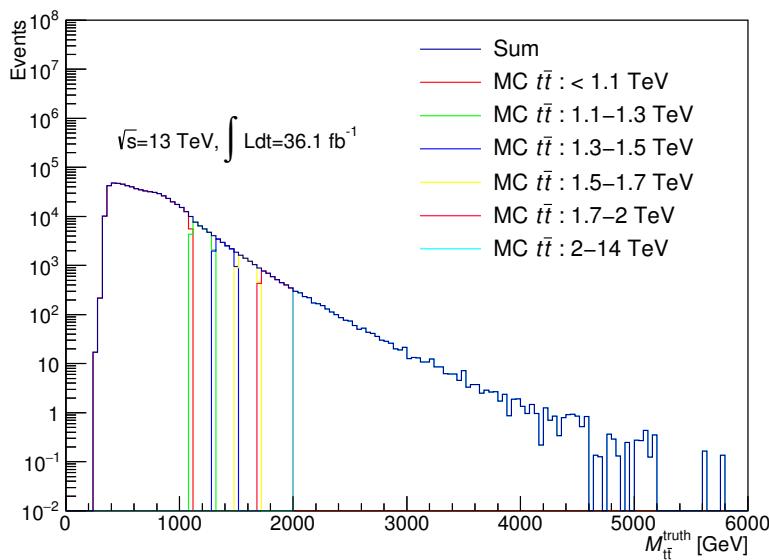

Figure 10: Distributions of the $t\bar{t}$ background (truth-level).

4.3. QCD multijets

Although the amount of QCD multi-jet background is estimated by a data driven method (Sec. 7). MC simulation samples are used for cross-checking.

As the QCD multi-jet samples, di-jet events are generated with PYTHIA 8.186, using the A14 set of tuned parameters for the underlying event and the LO NNPDF2.3 PDF set. Those samples are generated with a filtering on p_T of the truth leading jet, where jets are clustered using the anti- k_T algorithm with R=0.6 as can be seen in Fig. 11.

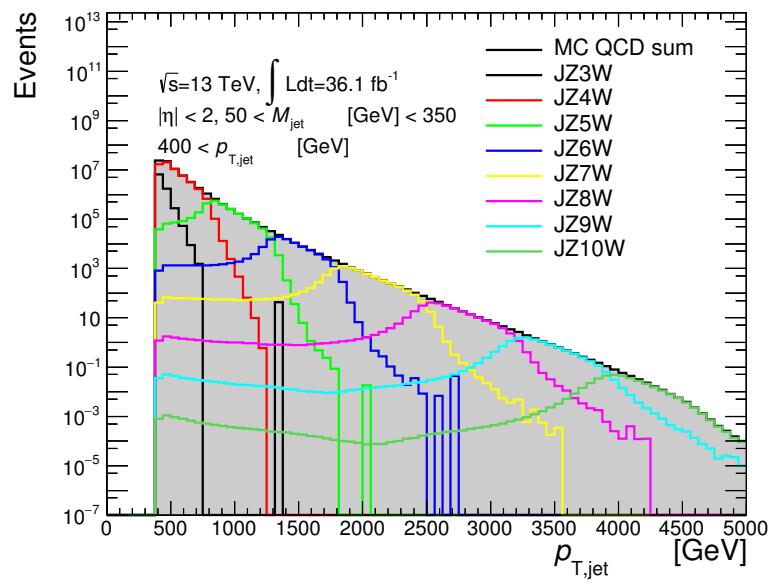

Figure 11: Distribution of reconstructed large- R jet p_T for the QCD multi-jet background in Monte Carlo simulation after selection of $|\eta| < 2$, $50 \text{ GeV} < m_{\text{jet}} < 350 \text{ GeV}$ and $p_{T,\text{jet}} > 400 \text{ GeV}$. The distribution is scaled to 36.1 fb^{-1} of data

5. Object definitions and reconstruction

A top quark decays into a W boson (decaying to two quarks) and a bottom quark. The analysis focuses on the high $m_{t\bar{t}}$ region and is performed in the boosted regime, in which hadronic decay products of a highly Lorentz-boosted top quarks are detected as a single large- R jet. A bottom quark can be tagged using a track jet within the large- R jet.

The analysis selects the events using refined and calibrated objects. These objects are described in the following section.

5.1. Small- R jets

Small- R jets are built from three-dimensional topological clusters of energy deposits in the calorimeter [76] at the electromagnetic energy scale using the anti- k_t algorithm [77] with a radius parameter $R = 0.4$. These jets are calibrated to the hadronic energy scale by applying p_T - and η -dependent corrections derived from MC simulations and in situ measurements obtained from $Z/\gamma + \text{jets}$ and multijet events at $\sqrt{s} = 13$ TeV [78]. Jets from pile-up interactions are suppressed by applying the jet vertex tagger (JVT) [79], which uses information about tracks associated with the hard-scatter and pile-up vertices, to jets with $p_T < 60$ GeV and $|\eta| < 2.4$. Events containing jets from calorimeter noise or non-collision backgrounds are removed by discarding events containing at least one jet failing the loose quality criteria defined in Ref. [80].

5.2. Large- R jets

Large- R jets are jets reconstructed from three-dimensional topological clusters of energy deposits in the calorimeter calibrated with the local cluster weighting (LCW) procedure [76] with the anti- k_T algorithm [77] with radius parameter $R=1.0$. The non-compensating response of the calorimeter and the energy loss in dead material and by out-of-cluster leakage for charged and neutral particles are corrected in the LCW procedure before reconstructing jets. The reconstructed jets are “trimmed” [81] to mitigate contributions from pile-up and soft radiation. In the trimming procedure, the jet constituents are reclustered into subjets using the k_t algorithm [82–84] with a radius parameter $R = 0.2$ and subjets with p_T less than 5% of the p_T of the parent jet are removed [85]. Finally, the large- R jets are formed from the four-vectors of the remaining subjets and selected by requiring $p_T > 200$ GeV and $|\eta| < 2.0$ for later use. For highly boosted top quarks, the mass calculation of a large- R jet containing the top-quark decay products deteriorates with increasing top p_T due to the limited angular resolution of the calorimeter. To overcome this effect the mass of the large- R jet, m_J , is calculated by combining the calorimeter energy measurement and the angular information from the ID, as described in Ref. [86]. The two leading large- R jets in the event are required to have $50 < m_{J1,2} < 350$ GeV.

5.3. Track jets

Track jets are built from charged particle tracks using the anti- k_t algorithm with a radius parameter $R = 0.2$. Tracks used in the reconstruction are selected by requiring that they are associated with the primary vertex, and have $p_T > 400$ MeV and $|\eta| < 2.5$. Track jets composed of at least two constituent

tracks, with $p_T > 10$ GeV and $|\eta| < 2.5$, are used to identify jets containing b -hadrons in the boosted analysis. In the dense environment characteristic of the boosted topology, the b -tagging is more efficient if performed on track jets than on the calorimeter jets [87]. The same b -tagging algorithm as small- R jets with 77% (tight) and 85% (loose) efficiency working points to b -quark-induced jets is employed. The training of multi-variate analysis used in the algorithm and the evaluation of systematic uncertainties associated with the track-jet b -tagging efficiency are performed separately from small- R calorimeter jets. The corresponding misidentification rates at the tight (loose) working point are 1.7% (5.3%) and 23.8% (40.5%) for light-flavor quarks and c -quarks, respectively.

5.4. Electrons

Electrons are reconstructed from clusters of EM calorimeter energy deposits matched to an ID track within $|\eta| < 2.47$, excluding the barrel and endcap transition region of $1.37 < |\eta| < 1.52$. The electron candidates are required to have $E_T > 25$ GeV and to satisfy the “tight” identification criteria defined in Ref. [88]. To suppress backgrounds from multijet production, the electron candidates are further required to be isolated from other hadronic activity in an event. This is achieved by requiring the sum of track p_T within a cone around the electron direction, excluding the track associated with the electron, to be less than 6% of the electron transverse momentum p_T^e . The cone radius is given by either $R = 10 \text{ GeV}/p_T^e$ or $R = 0.2$, whichever is smaller.

5.5. Muons

Muons are reconstructed by combining tracks reconstructed in both the ID and to muon spectrometer. The muon candidates are required to have $p_T > 25$ GeV and $|\eta| < 2.5$, and satisfy the “medium” quality requirements defined in Ref. [89]. The muons are also required to be isolated by using the same track-based isolation conditions as for electron, except that the choice of $R = 0.2$ is replaced with $R = 0.3$.

Both electron and muon candidate tracks are required to be associated with the primary vertex by criteria on the longitudinal and transverse impact parameters. To avoid the misidentification of jets as electrons, the closest small- R jet within $\Delta R_y = \sqrt{(\Delta y)^2 + (\Delta\phi)^2} < 0.2$ around a reconstructed electron is removed.¹ If an electron is then found within $\Delta R_y < 0.4$ around a jet, the electron is removed. If a muon is found within $\Delta R_y < 0.04 + 10 \text{ GeV}/p_T^\mu$ (where p_T^μ is the muon transverse momentum) around a jet, the muon is removed if the jet contains at least three tracks, otherwise the jet is removed.

¹ The rapidity is defined as $y = \frac{1}{2} \ln \frac{E+p_z}{E-p_z}$ where E is the energy and p_z is the longitudinal component of the momentum along the beam pipe.

6. Event Selections

6.1. Pre-selection

The ATLAS detector recorded the data at a center-of-mass energy of 13 TeV in 2015 and 2016. The total integrated luminosity is 36.07 fb^{-1} , and the uncertainty in the luminosity measurement is 2.1%. Events were collected under stable conditions for the beams and the detector, and all events used in this analysis were selected by a single large- R jet trigger which nominal p_T . Thresholds were 360 GeV and 420 GeV in 2015 and 2016, respectively.

The selected events are required to have at least one primary vertex (PV) that has at least two associated ID tracks, each with the transverse momenta $p_{T,track} > 0.4 \text{ GeV}$, and be consistent with the beam spot of the pp colisions. For events with more than one PV candidate, that with the largest $\Sigma p_{T,track}^2$ is chosen as PV of the hard-scattering.

In order to reduce its size, the sample was skimmed before studying the analysis detail. The selections applied are as follows.

- At least one large- R jet ($p_T > 300 \text{ GeV}$ and $|\eta| < 2.2$) and at least one small- R jet ($p_T > 300 \text{ GeV}$ and $|\eta| < 2.7$)
- Both small- R and large- R jets are passed ΔR between large- R jet and small- R jet < 1.0 (At least one pair is required)
- Soft lepton veto : If an event has at least one lepton (electron or muon) with $p_T > 30 \text{ GeV}$ and $|\eta| < 2.4$, the event is vetoed

The other pre-selection are :

- A good condition flag of the calorimeteres is required.
- Events are rejected if there are leptons with $p_T > 25 \text{ GeV}$ to ensure that both top quarks decay hadronically.
- The transverse momentum of the leading large- R jet has to be greater than 500 GeV (to ensure 100% trigger efficiency (see Fig. 12),) and that for the sub-leading large- R jet has to be greater than 400 GeV to ensure that we deal with mostly contained top quarks and have better mass resolution (see Fig. 13).
- Events containing jets which fail the quality criteria are rejected (Sec. 5)

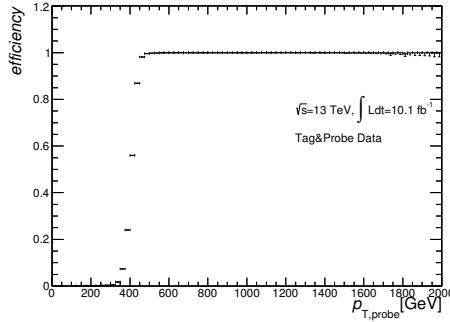

Figure 12: Trigger efficiency measured for the HLT_j420_a10r_L1J100 trigger, which requires a large- R jet (anti- k_T , $R=1.0$) with $p_T > 420\text{GeV}$. To measure this efficiency, offline jet object is matched with an HLT jet object within a cone of $\Delta R < 0.04$. The tag-and-probe method is used to avoid possible trigger bias. Two offline jets are required in an event, and the one is required to be matched with the trigger object (tag), and then the other is examined if it is matched with the trigger object (probe).

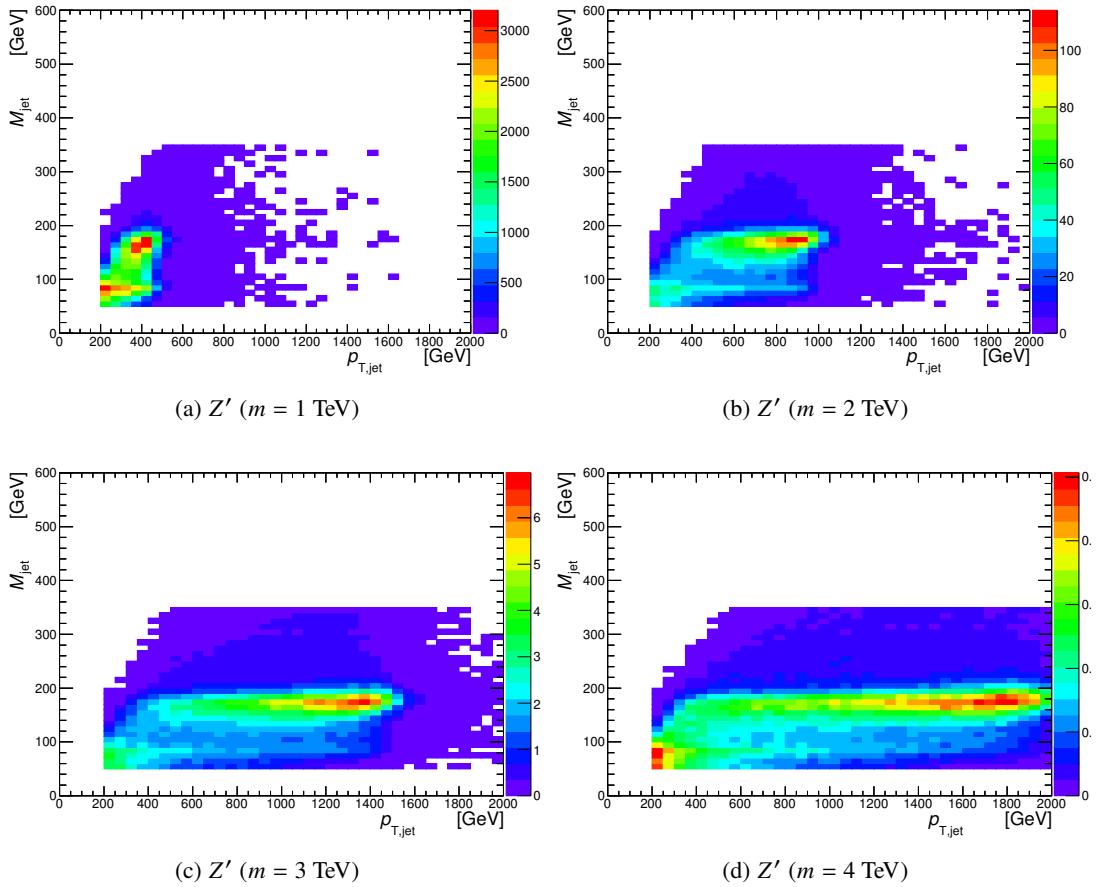

Figure 13: Two dimensional distributions of the reconstructed large- R jet p_T and jet mass before pre-selection.

- Each of the two highest- p_T large- R jets has to include at least 1 track jet with loose b-tag quality (85% working point) within ΔR (large- R jet, track jet) < 1.0. (Fig. 14 shows the distribution of the minimum angle difference in R between a large- R jet matched to a top quark and track jet matched to a bottom quark in the standard model $t\bar{t}$ Monte Carlo. It shows that a requirement of ΔR (large- R jet, track jet) is good enough to correctly match a top quark jet and a bottom quark jet.) The requirements of loose b-tagging is to largely reduce the number of the multijet events which contain no top decay. The b-tagging efficiency as a function of p_T is estimated using the MC simulation, and is shown in Fig. 15. The b-tagging fake rate, b-tagging efficiency for non-b track jet, is shown in Fig. 16. This is a fraction of track jets which are not matched with a truth bottom quark but b-tagged in the $t\bar{t}$ MC. The fake rate in $t\bar{t}$ events can be higher than those for other samples Non-b jets can be charm quark jets from W boson in top decays and c-jets have higher fake rate. Table 6 shows the efficiency of b-tag and rejection rates of c-flavor jets and light-flavor jets.

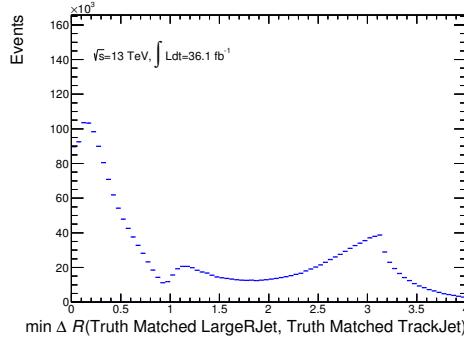

Figure 14: Distribution of the minimum angle difference in R between a large- R jet and a track jet, matched to a top quark and to a bottom quark respectively, in the standard model $t\bar{t}$ Monte Carlo. Reconstructed objects (jets) are required to match with corresponding truth-level objects (quarks). The large- R jet is required to be matched with the truth top quark with a cone $\Delta R < 0.1$. The track jet is required to be matched with the closest truth bottom quark with a cone $\Delta R < 1.0$.

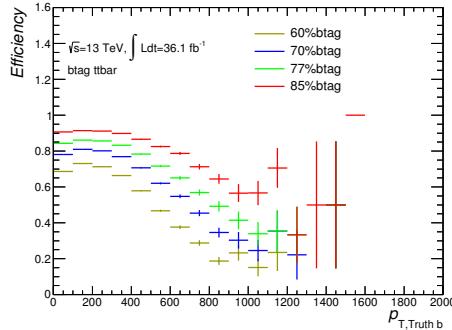

Figure 15: B-tagging efficiency for track jets as a function of truth-level b-quark p_T . The b-tagging efficiency is determined per track jet matched with the closest truth b quark with a cone $\Delta R < 0.1$ using the standard model $t\bar{t}$ Monte Carlo simulation. Track jets are required to be within the detector coverage, $|\eta| < 2.5$, and $p_T > 10$ GeV.

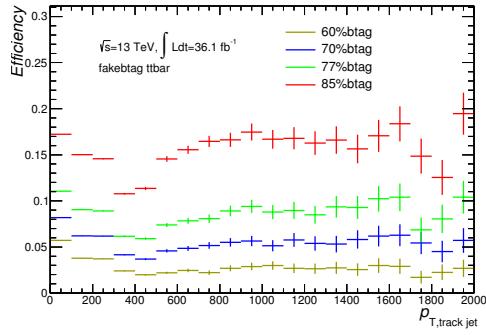

Figure 16: B-tagging fake rate for track jets as a function of reconstructed track jet p_T . The b-tagging fake rate is the fraction of track jets which are not coming from a b-quark but are tagged as a b quark. The efficiency is determined per track jet not matched with the closest truth b quark with a cone $\Delta R < 0.1$ using the standard model $t\bar{t}$ Monte Carlo simulation. Track jets are required to be within the detector coverage, $|\eta| < 2.5$, and $p_T > 10$ GeV.

b-jet efficiency[%]	c-jet Rejection	Light-jet Rejection	τ Rejection
85%	2.47(40.5%)	18.97(5.3%)	3.75
77%	4.21(23.8%)	57.9(1.7%)	8.09
70%	7.09(14.1%)	119.69(0.85%)	17.25
60%	16.16(6.2%)	276.16(0.36%)	53.47

Table 6: Efficiency of b-tag and rejection rates ???. The number in the bracket next to the rejection rate is the fake efficiency (inverse of the rejection).

6.2. Event selection

6.2.1. Angular difference selection

The decays of a new particle products two top quarks back-to-back. The angular difference in azimuthal angle (ϕ) between the leading and sub-leading large- R jets has to be larger than 1.6. Figure 17 shows the distribution of angular difference of the two large- R jets, $\Delta\phi_{\text{di-largeRjet}}$, in the signal and background MC samples.

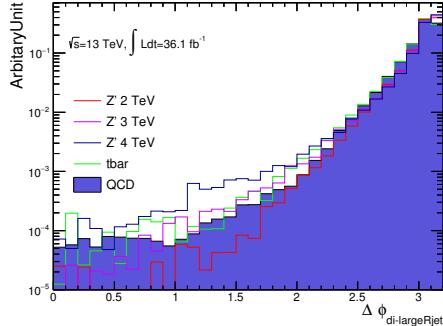

Figure 17: Distribution of the angle difference in ϕ between the leading and sub-leading large- R jets in the signal and background Monte Carlo samples after pre-selection.

6.2.2. Large- R jet τ_{32}^{wta} -likelihood ratio

τ_{32}^{wta} is a jet substructure variable defined using the N-subjettiness τ_N [90, 91]. The N-subjettiness is based on the reconstruction of exactly N sub-jets with the k_T jet algorithm [82–84] from the constituents of a jet. The τ_N is defined as

$$\tau_N = \frac{1}{d_0} \sum_k p_{T,k} \times \min(\delta R_{1,k}, \delta R_{2,k}, \dots, \delta R_{N,k}), \quad (35)$$

where $d_0 = \sum_k p_{T,k} \times R$, R is the radius parameter of the jet, $p_{T,k}$ is the transverse momentum of the constituent k , and $\delta R_{i,k}$ is the distance between the sub-jets i and the constituent k . The τ_{32} is then defined as

$$\tau_{32} = \frac{\tau_3}{\tau_2} \quad (36)$$

In order to obtain an observable independent of the recoil of soft radiation inside the jet, the sub-jets are reconstructed with a winner-take-all (WTA) recombination scheme [92]. The N-subjettiness variable τ_N expresses how well a jet can be described as containing N or fewer sub-jets. If $\tau_N \sim 0$, the jet has N (or fewer) sub-jets, while jets with $\tau_N >> 0$ have more sub-jets. The τ_{32}^{wta} allows discrimination between jets with a three-prong structure and those with a two-prong structure. Since top quarks decay into three particles, a large- R jet of a top quark candidate is expected to have a three-prong structure, and τ_{32}^{wta} is useful for the top quark identification.

Probability density functions are defined based on the τ_{32} distributions and a likelihood ratio is calculated for each events. Events are selected and categorized using the likelihood ratios (Sec. 6.3.3 for the categorization).

Two large- R jets (the leading and sub-leading large- R jets) are selected as top candidates. As the τ_{32}^{wta} variable is defined per large- R jet, a combination of two τ_{32}^{wta} variables has to be dealt with in each event. To minimize the complexity of dealing with the two τ_{32}^{wta} values, a probability density function for an event $P(\tau_{32,i}^{wta}, \tau_{32,j}^{wta})$ is defined as

$$P(\tau_{32,i}^{wta}, \tau_{32,j}^{wta}) = P(\tau_{32,i}^{wta}) \times P(\tau_{32,j}^{wta}), \quad (37)$$

where $P(\tau_{32,i}^{wta})$ denotes a probability density function for a single jet i . It is produced by templates of the τ_{32}^{wta} distributions obtained from Z' MC for the signal and QCD multijet MC for the background. A τ_{32}^{wta} -likelihood ratio is then produced using the signal and background probability density functions as

$$\equiv \frac{L(P(\tau_{32,i}^{wta}, \tau_{32,j}^{wta}) | \tau_{32,i}^{wta}, \tau_{32,j}^{wta})}{P_{\text{signal}}(\tau_{32,i}^{wta}, \tau_{32,j}^{wta}) + P_{\text{background}}(\tau_{32,i}^{wta}, \tau_{32,j}^{wta})}, \quad (38)$$

where $L(P(\tau_{32,i}^{wta}, \tau_{32,j}^{wta}) | \tau_{32,i}^{wta}, \tau_{32,j}^{wta})$ is the τ_{32}^{wta} - likelihood ratio. The τ_{32}^{wta} - likelihood ratio is calculated per event.

Figure 18 shows the two-dimensional distribution of the τ_{32}^{wta} for the leading and sub-leading jets. No correlation between the two jets is seen.

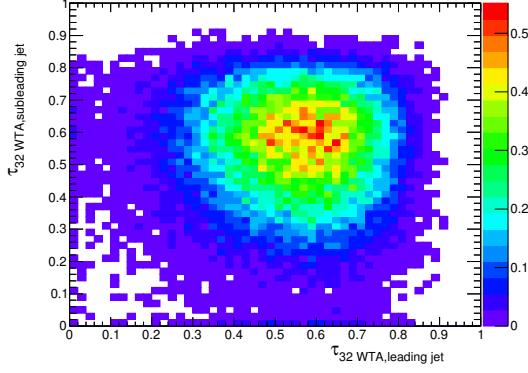

Figure 18: Two-dimensional τ_{32}^{wta} distribution of the leading large- R jet and the sub-leading large- R jet for Z' 3 TeV.

Figure 19 shows the τ_{32}^{wta} distribution of each Z' Monte Carlo sample after pre-selection up to Sec. 6.1. The Monte Carlo samples of Z' with a mass larger than 2.5 TeV show the similar shape of τ_{32}^{wta} .

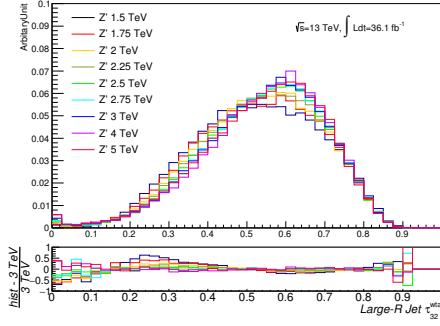

Figure 19: Distribution of τ_{32}^{wta} after pre-selection up to Sec. 6.1 in the signal Monte Carlo samples shown for reconstructed jets. The top panel shows the distribution and the bottom panel shows the relative difference with respect to the Z' 3 TeV sample.

The signal template is made using the several Z' Monte Carlo samples with Z' mass larger than 2.5 TeV in order to obtain statistics.

Figure 20 shows the distributions of τ_{32}^{wta} for Monte Carlo QCD multijet events and data after the subtraction of the SM $t\bar{t}$ events estimated from the MC sample. Both are shown for events after the pre-selection up to Sec. 6.1. Distributions of the Monte Carlo QCD multijet events are in good agreement with data after the $t\bar{t}$ subtraction.

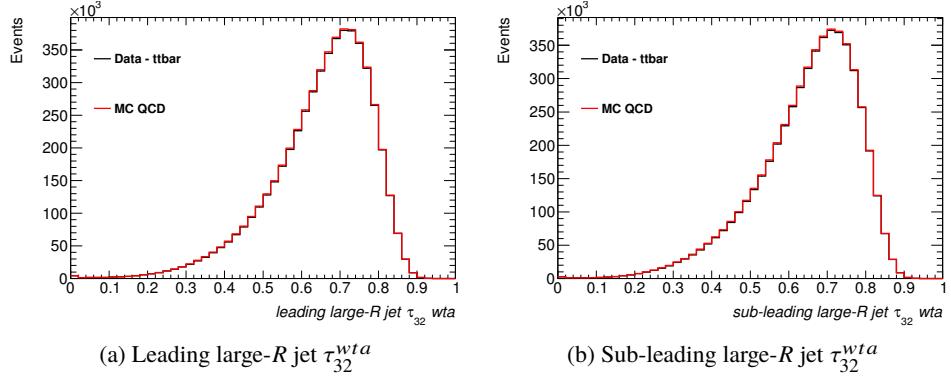

Figure 20: Distribution of τ_{32}^{wta} for Monte Carlo QCD multijet events and data after subtraction of the SM $t\bar{t}$ events estimated from the Monte Carlo sample. The pre-selections described in the Sec. 6.1 are applied on the both samples. The distributions are shown separately for the leading large- R jets and the sub-leading large- R jets

Figure 21 shows the resulting distribution of the τ_{32}^{wta} -likelihood ratio for the Z' MC and multijet MC samples.

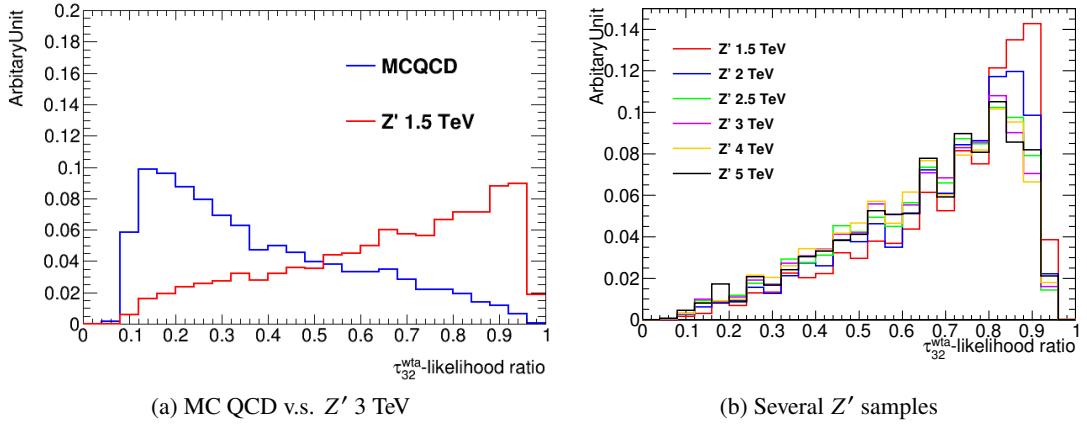

Figure 21: Distribution of the likelihood ratio formed from two τ_{32}^{wta} histograms. (a) Distributions of the likelihood ratios of the Z' MC sample the multijet MC sample. (b) Distributions of the likelihood ratios of the Z' MC samples with different Z' mass values.

Correlations between the τ_{32}^{wta} -likelihood ratio and other kinematics variables are checked in Fig. 22 and Fig. 23. The variables checked are jet p_T , η and $m_{t\bar{t}}$. No significant correlation between the τ_{32}^{wta} -likelihood ratio and the other kinematic variables is found. There is only small correlation between the large- R jet η and the τ_{32}^{wta} -likelihood ratio.

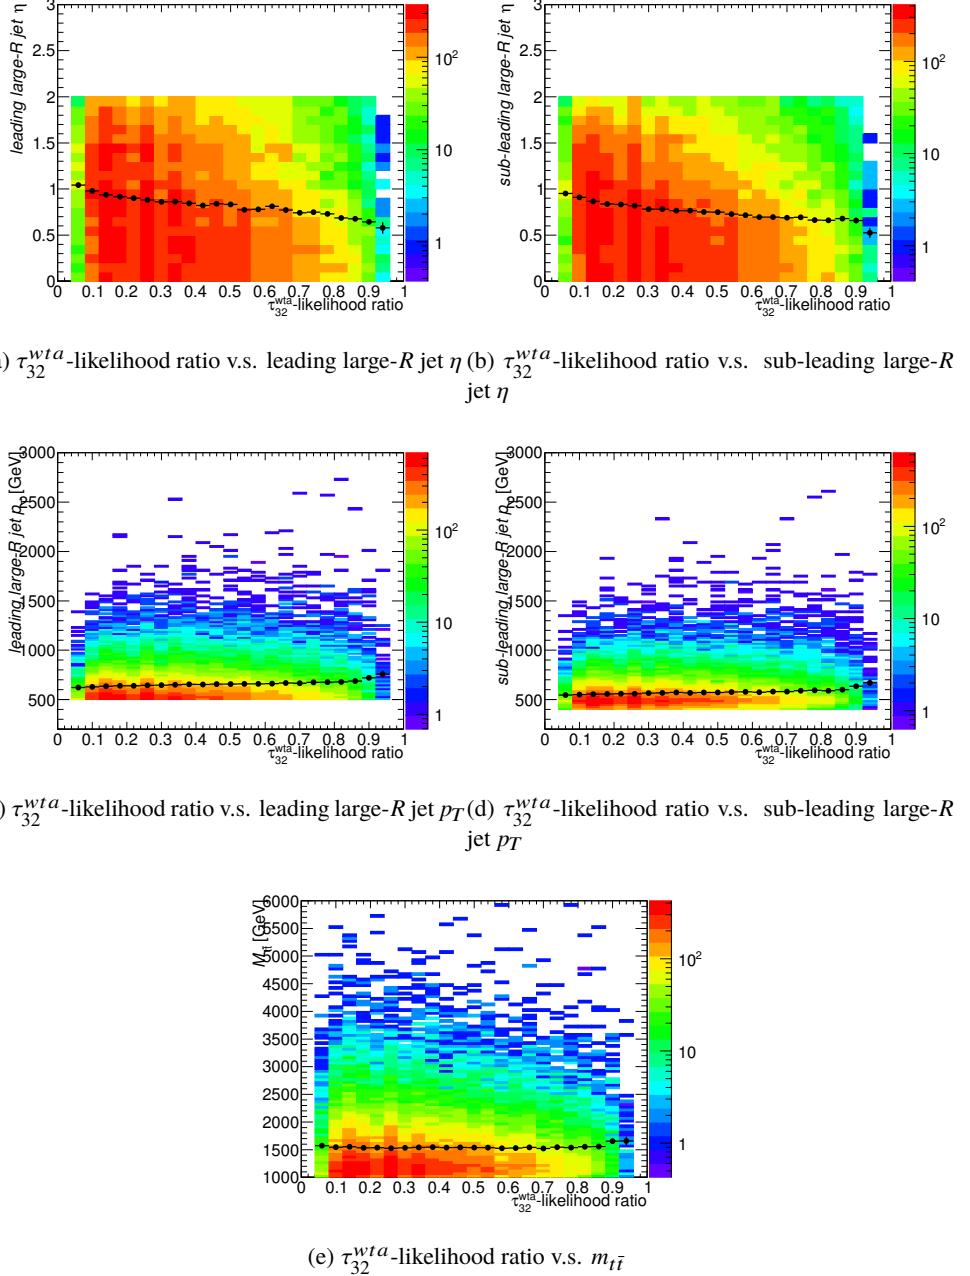

Figure 22: Correlation between τ_{32}^{wta} -likelihood ratio and other kinematic variables, for data after the subtraction of $t\bar{t}$ contribution estimated using MC simulation in a region which is enhanced multijet events with no tight b-tagging requirement and large- R jet mass cut ($50\text{GeV} < m_{\text{large-}R\text{jet}} < 140\text{GeV} \parallel 190\text{GeV} < m_{\text{large-}R\text{jet}} < 350\text{GeV}$). (a) leading large- R jet η . (b) sub-leading large- R jet η . (c) leading large- R jet τ_{32}^{wta} . (d) sub-leading large- R jet τ_{32}^{wta} . (e) reconstructed $t\bar{t}$ mass. Markers show the mean values of the kinematic variable in each bin of the likelihood ratio.

We found a small bias in η and $m_{t\bar{t}}$ for τ_{32}^{wta} -likelihood ratio below 0.35 as can be seen in Figs 23. Therefore, only events with τ_{32}^{wta} -likelihood ratio above 0.35 are selected. The selected events are categorised in Loose, Medium and Tight based on the values of the likelihood ratio (See Sec. 6.3).

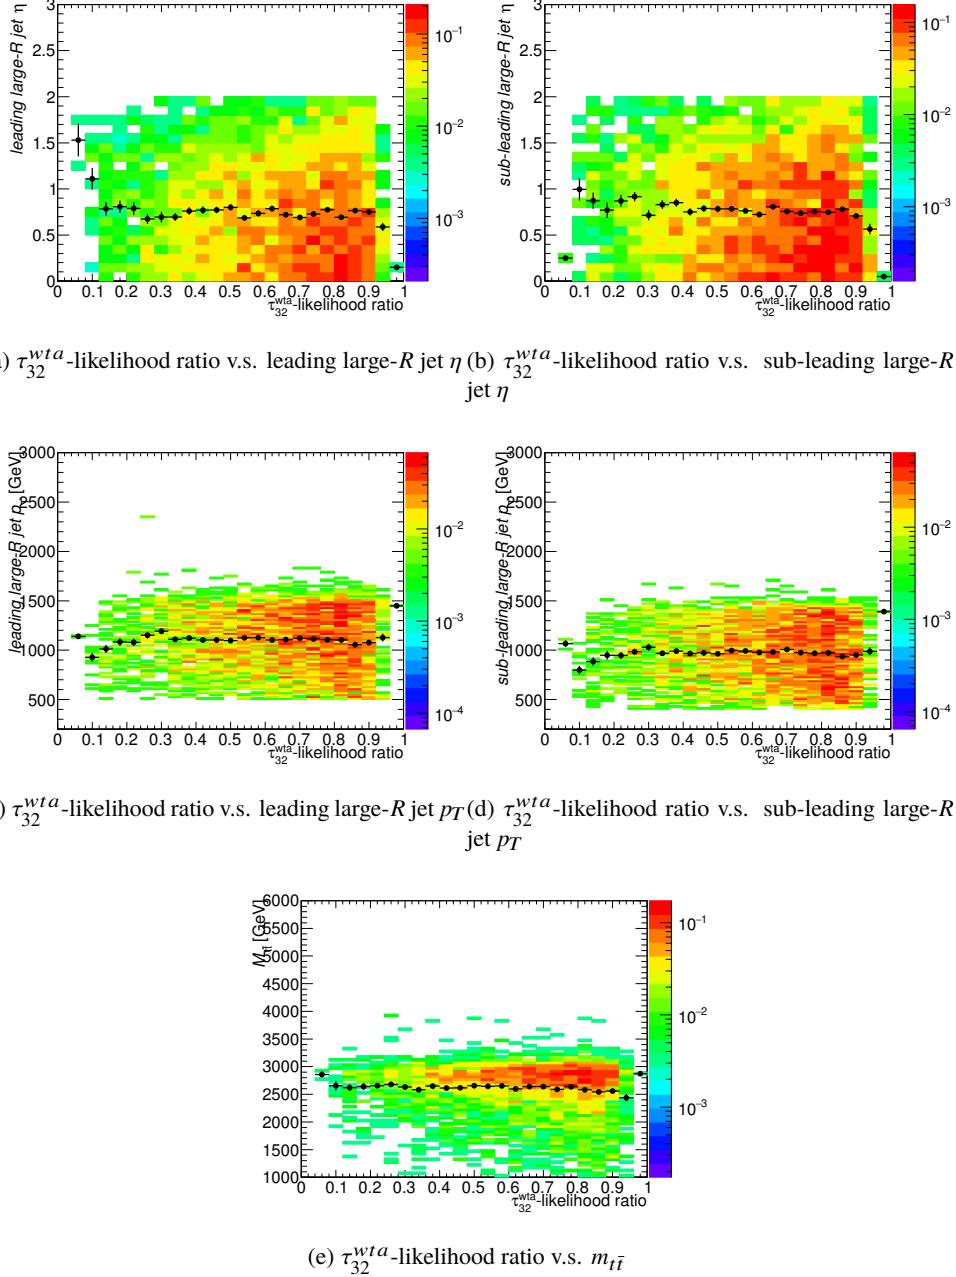

Figure 23: Correlation between τ_{32}^{wta} -likelihood ratio and other kinematics for Z' 3 TeV in a region after selection of two tight b-tagging requirement and large- R jet mass cut ($140\text{GeV} < m_{\text{large-}R\text{jet}} < 190\text{GeV}$). (a) leading large- R jet η . (b) sub-leading large- R jet η . (c) leading large- R jet τ_{32}^{wta} . (d) sub-leading large- R jet τ_{32}^{wta} . (e) reconstructed $t\bar{t}$ mass. Markers show the mean values of the kinematic variable in each bin of the likelihood ratio.

6.2.3. Large- R jet mass selection

The leading and sub-leading large- R jets are required to have their reconstructed mass, m_{jet} , in the range [140:190] GeV, consistent with the expected top quark mass. The criteria for the m_{jet} is optimized by scanning the Z' signal sensitivity by varying the range boundaries. The sensitivity is defined as Eq. (39).

$$\text{Sensitivity} = \frac{S}{\sqrt{S + B + (B \times \Delta)^2}}, \quad (39)$$

where S denotes the number of signal events, B denotes the number of background events, and Δ denotes the systematic uncertainty, where we use $\Delta=20\%$ during the scans.

The stability of the criteria is checked in Fig. 24 and Fig. 25 for lower and upper boundaries respectively, using the Z' MC samples with $m_{Z'} = 2.5, 3$ and 4 TeV. The value of the coordinate on the vertical axis in Fig. 24 and Fig. 25 is the sensitivity, and the value of the coordinate on the longitudinal axis is the range boundaries. From those figures, sensitivity is stable and higher than other boundary around 140 GeV and 190 GeV.

The optimized values are found to be 140 GeV for lower mass cut, and 190 GeV for higher mass cut. This study uses events with the τ_{32}^{wta} -likelihood ratio greater than 0.8 (after the pre-selection described in 6.1).

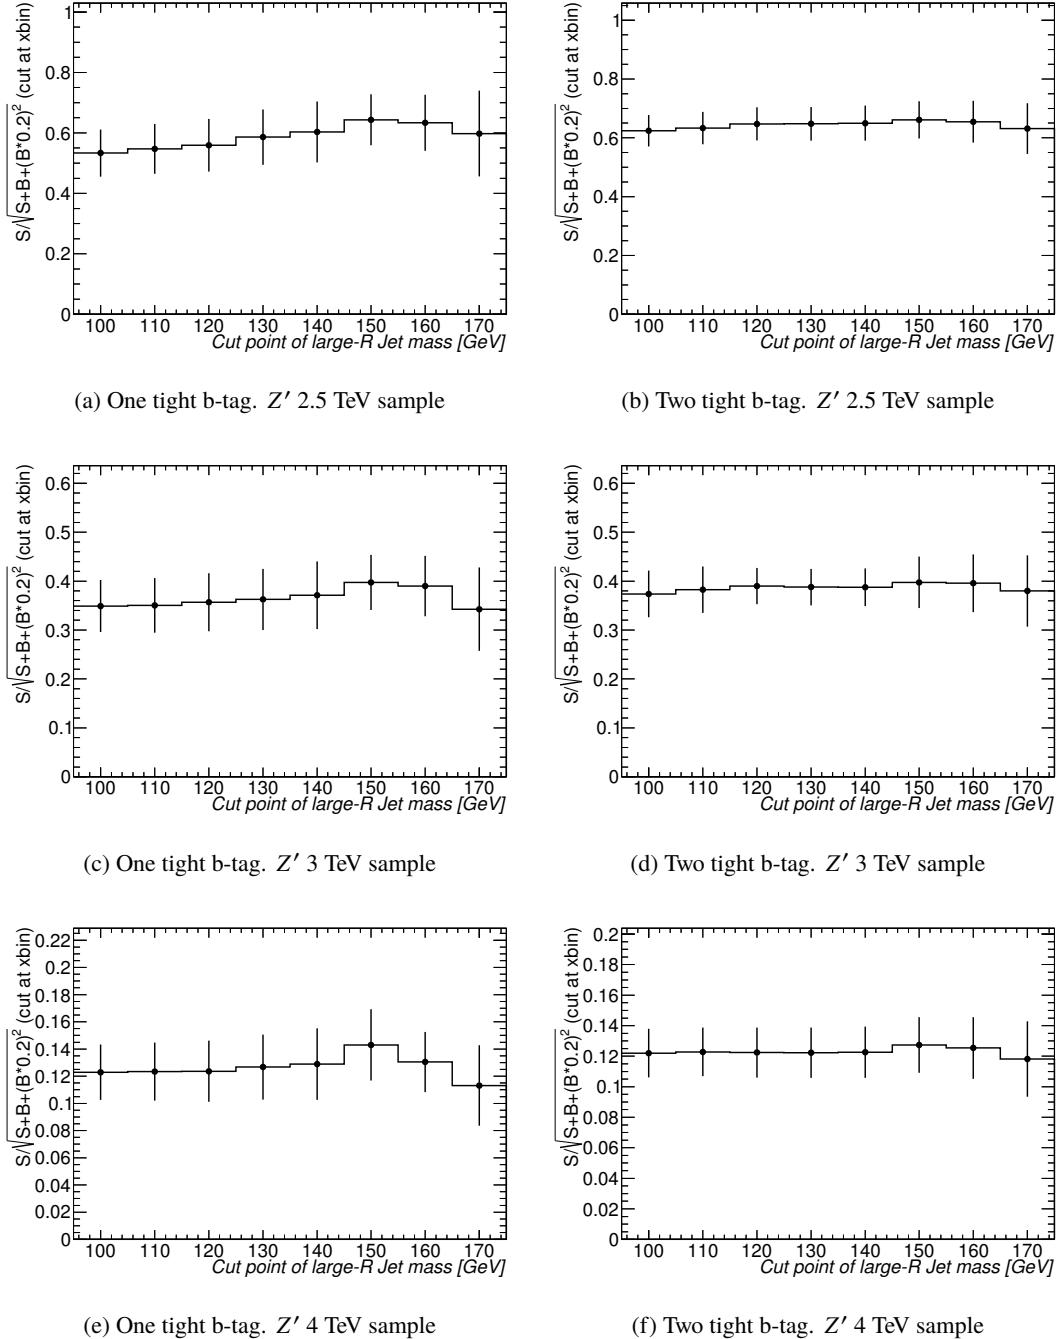

Figure 24: Sensitivities as a function of the lower boundary of the m_{jet} requirement. The upper boundary of $m_{\text{jet}} < 190$ GeV and $\tau_{32}^{\text{wta}}\text{-likelihood} > 0.8$ are applied. They are shown separately for events containing one b-tag jet and those with two b-tag jets and for the Z' MC samples with $m_{Z'} = 2.5, 3$ and 4 TeV (The pre-selection described in 6.1).

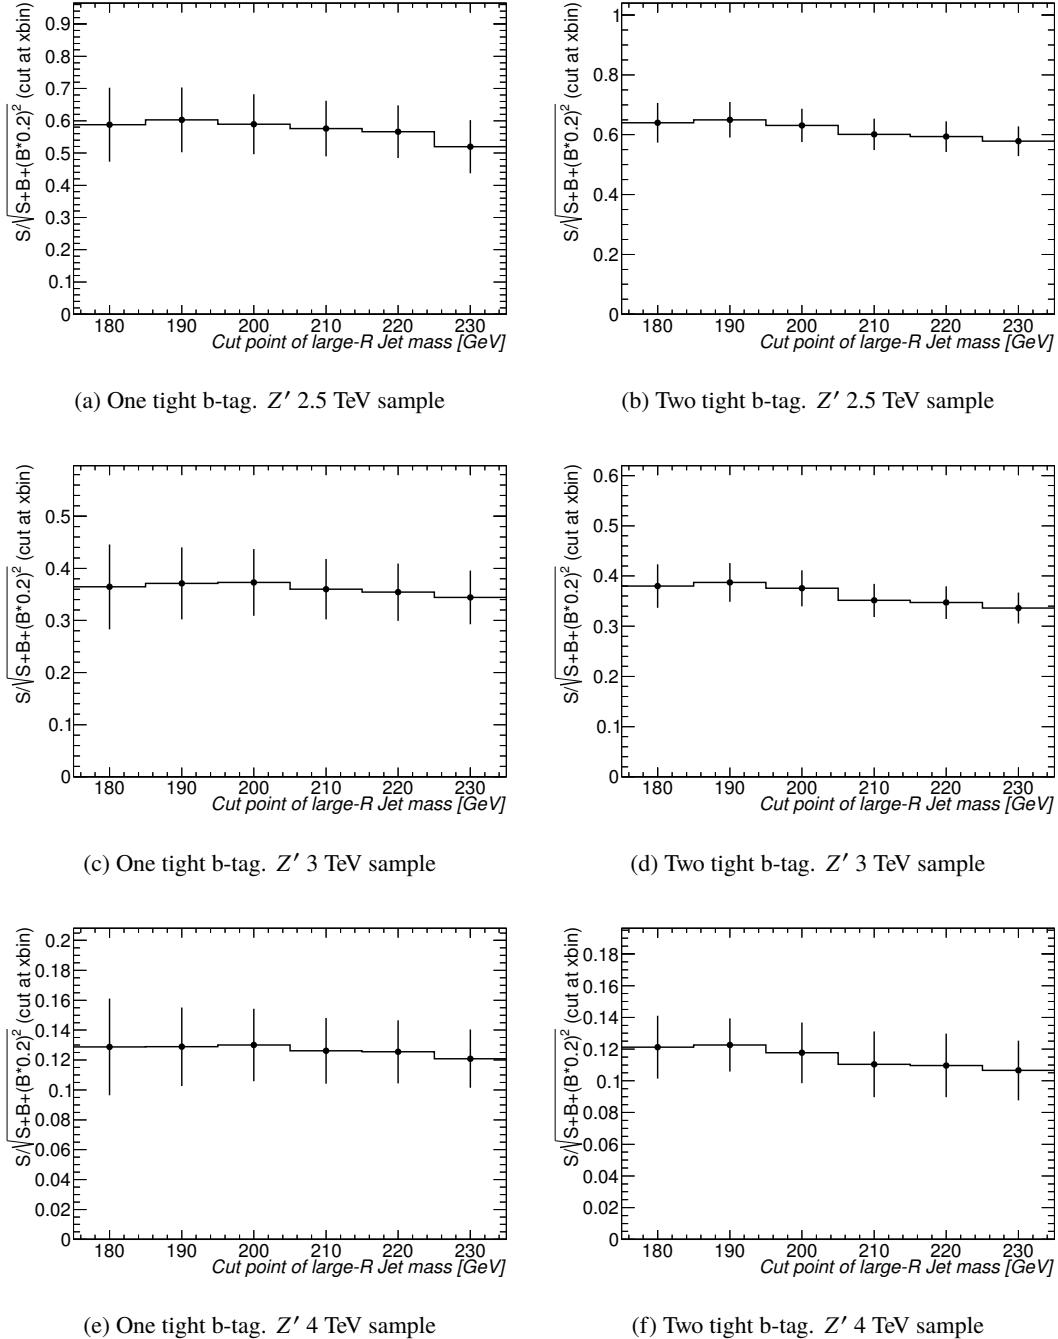

Figure 25: Sensitivities as a function of the lower boundary of the m_{jet} requirement. The upper boundary of $140 \text{ GeV} < m_{\text{jet}} < 160 \text{ GeV}$ and $\tau_{32}^{\text{wta-likelihood}} > 0.8$ are applied. They are shown separately for events containing one b-tag jet and those with two b-tag jets and for the Z' MC samples with $m_{Z'} = 2.5, 3$ and 4 TeV (The pre-selection described in 6.1).

6.2.4. Selection efficiencies

If a large- R jet satisfies $140 < m_{jet} < 190$ GeV and the event satisfies τ_{32}^{wta} -likelihood ratio > 0.65 , the jet is considered as a top-quark. Figure 26 shows the efficiency of the large- R jet mass selection and τ_{32}^{wta} -likelihood ratio selection. Figure 27 shows the efficiency of each selection.

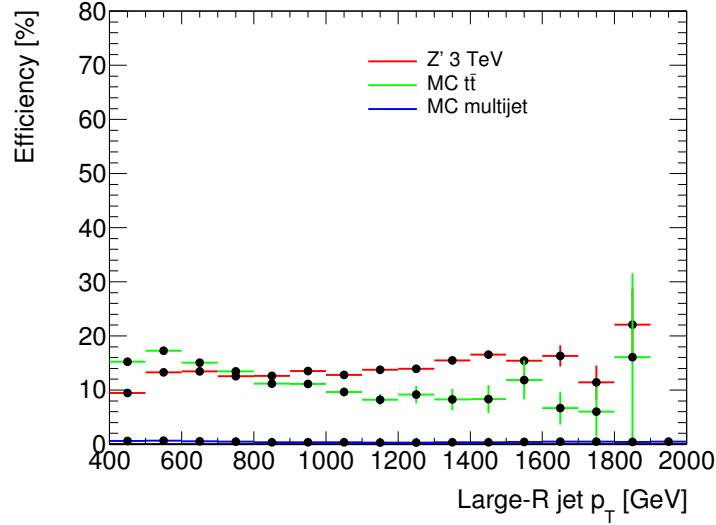

Figure 26: Top quark tagging efficiency. The pre-selection is applied and at least 2 large- R jets are for the denominator. For the numerator, $140 \text{ GeV} < m_j < 190 \text{ GeV}$ and τ_{32}^{wta} -likelihood > 0.65 are additionally for numerator.

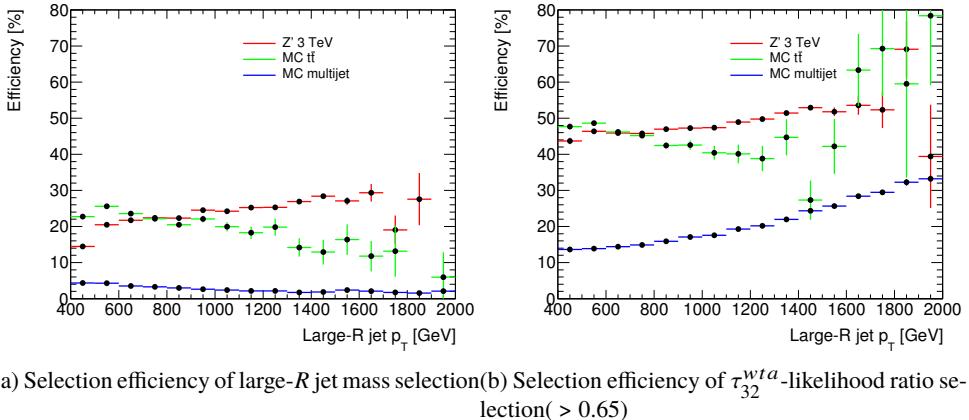

Figure 27: Selection efficiency of large- R jet mass and τ_{32}^{wta} -likelihood ratio selection for MC $t\bar{t}$ and Z' 3 TeV as a function of large- R jet p_T . Denominator is the events passing pre-selection. Numerator is the events passing pre-selection and each selection.

There is a difference between SM $t\bar{t}$ and Z' 3 TeV MC samples. It is caused by the difference of loose b-tagging efficiency as a function of the large- R jet η distribution between $t\bar{t}$ and Z' 3 TeV samples. The high p_T events of Z' 3 TeV are mainly at the central region, and the low p_T events of Z' 3 TeV are mainly at forward region as seen in Fig 28.

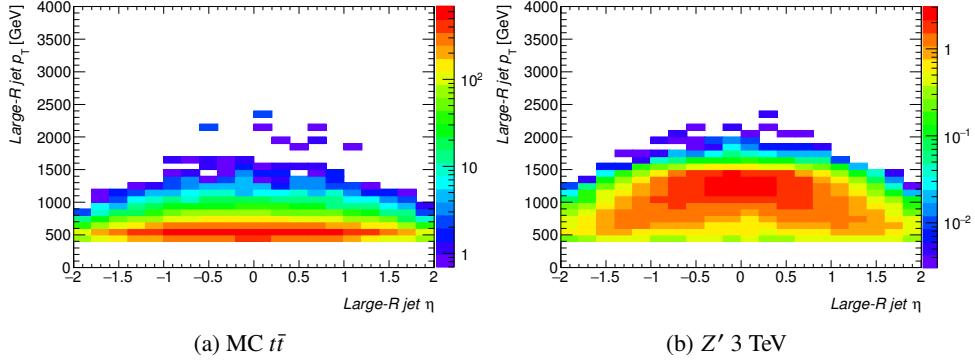

Figure 28: 2D distribution for large- R jet p_T V.S. large- R jet η for MC $t\bar{t}$ and Z' 3 TeV

The distribution of SM $t\bar{t}$ events is uniform compared to the Z' sample. The selection efficiency of loose b-tag as a function of large- R jet p_T is also checked in Fig. 29. From the figure, the loose b-tag selection cause the difference of efficiency for SM $t\bar{t}$ and the Z' sample because of the difference of the large- R jet η distribution.

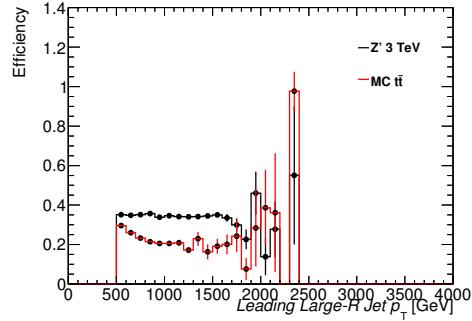

Figure 29: Selection efficiency of the loose b-tag selection for MC $t\bar{t}$ and Z' 3 TeV as a function of large- R jet p_T .

Figure 30, 31 show the acceptance and the efficiency of the event selection. Acceptance is defined as “Truth events after truth the selections” over “Truth events with pre-selection”. The truth selections are $|\eta_t| < 2.0$, $p_{T,\text{leading}t} > 500$ GeV, $p_{\text{sub-leading}t} > 400$ GeV, $140 \text{ GeV} < m_t < 190$ GeV, $|\eta_b| < 2.5$, $p_{T,b} > 10$ GeV, $\Delta\phi(\text{top, anti} - \text{top}) < 1.6$, $\Delta R(t, b) < 1.0$ and $m_{t\bar{t}} > 1$ TeV (t denote truth top quark object and b denote truth bottom quark object). The truth selection also include. Derivation cut is included in following cut.

- At least one large- R jet ($p_T > 300$ GeV and $|\eta| < 2.2$) and at least one small- R jet ($p_T > 300$ GeV and $|\eta| < 2.7$)
- At least one large- R jet or small- R jet (passing a cut ΔR between large- R jet and small- R jet < 1.0)
- Soft lepton veto : If a event has at least one electron ($p_T > 30$ GeV and $|\eta| < 2.4$) or at least one muon ($p_T > 30$ GeV and $|\eta| < 2.4$)

The acceptance at the low $m_{t\bar{t}}$ region is low because of the kinematic boundary of the analysis, i.e. the jet p_T is required to be greater than 500 GeV for the leading jet and 400 GeV for the sub-leading jet, and also the existence of a b-jet in the large- R jet is required.

Efficiency is defined as “Truth events after reco and truth selections” over “Truth events after truth selection”.

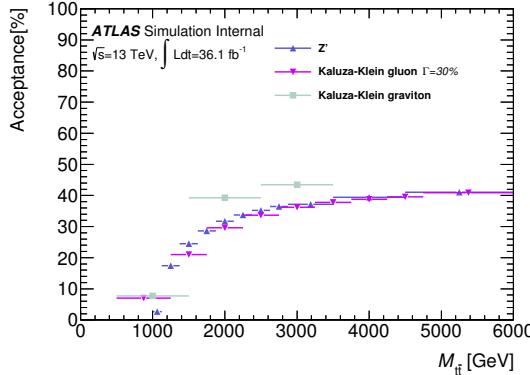

Figure 30: Acceptance show for Z' , KK gluon and KK graviton. Both truth top quarks are required $140 \text{ GeV} < m_j < 190 \text{ GeV}$, $p_{T,\text{top}} > 400$, $p_{T,\text{leadingtop}} > 500$, $|\eta_{\text{top}}| < 2.0$, $\Delta R(\text{top}, \text{bottom}) < 1.0$, $\Delta\phi_{t\bar{t}}, p_{T,\text{bottom}} > 10 \text{ GeV}$, $|\eta_{\text{bottom}}| < 2.5$, $\Delta R(t, b) < 1.0$ and $m_{t\bar{t}} > 1 \text{ TeV}$ for the numerator. Only derivation cut is applied for the denominator.

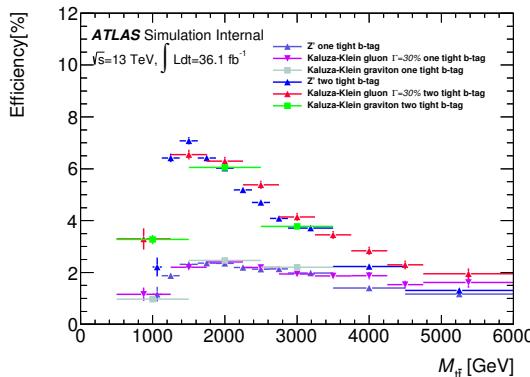

Figure 31: Efficiency as a function of truth $m_{t\bar{t}}$. In addition to the event selection described in the text, exactly one or two tight b-tagging, large- R jet mass [140 GeV:190 GeV] and $0.65 < \tau_{32}$ -likelihood ratio are required for the numerator. Both truth top quarks are required $140 \text{ GeV} < m_j < 190 \text{ GeV}$, $p_{T,\text{top}} > 400$, $p_{T,\text{leadingtop}} > 500$, $|\eta_{\text{top}}| < 2.0$, $\Delta R(\text{top}, \text{bottom}) < 1.0$, $\Delta\phi_{t\bar{t}}, p_{T,\text{bottom}} > 10 \text{ GeV}$ and $|\eta_{\text{bottom}}| < 2.5$ for the denominator.

Results of efficiency (two tight b-tag) times acceptance for each signal model and each mass point are summarized in Table 7.

$m_{t\bar{t}}$ point [GeV]	1000	2000	3000	4000	5000
Z' 3 TeV	2.2%	6.1%	3.8%	2.3%	1.8%
RS-Graviton 3 TeV	3.3%	6.1%	3.9%	—	—
KK-gluon 3 TeV	3.2%	6.3%	4.2%	2.9%	2.0%

Table 7: Efficiency \times acceptance for each signal model. Two tight b-tag is applied.

6.3. Event categories

Event selections are optimized with respect to the signal sensitivity as mentioned earlier. Our events are categorized by types of b-tag conditions, τ_{32}^{wta} -likelihood ratio selections and m_{jet} selections to define the signal region and to estimate the amount of multijet background from data.

The b-tag categories are defined as:

- No tight b-tag : both large- R jets have associated loose b-tagged track jets, but have no associated tight b-tagged track jets. Multijet background contributions are dominant in this category, therefore this category is used to obtain the template shape of the shape multijet background.
- One tight b-tag : only one of the two large- R jets has an associated tight b-tagged track jet. Having a lot of signal events, a part of this category is included in the signal region.
- Two tight b-tag : both large- R jets have associated tight b-tagged track jets. This category is the most sensitive to the signal among the b-tag categories, and is included in signal region.

where 'tight' b-tagging is defined as the 77% b-tag efficiency track jet working point.

Three categories are defined based on τ_{32}^{wta} -likelihood ratio requirements as mentioned before (see Section 6.3.2): And the categories based on the m_{jet} selection are mentioned in the Sec. 6.3.1).

6.3.1. m_{jet} categories

We define m_{jet} -categories based on the m_{jet} values of the leading and sub-leading large- R jets. The definition is illustrated in Fig. 32. The region R0 has the largest amount of the signal events, and the region R3 also has reasonable sensitivity. Therefore, the regions R0 and R3 are to be used as the signal region. Details are summarized in the later section (Table 8 in Sec. 6.3.3).

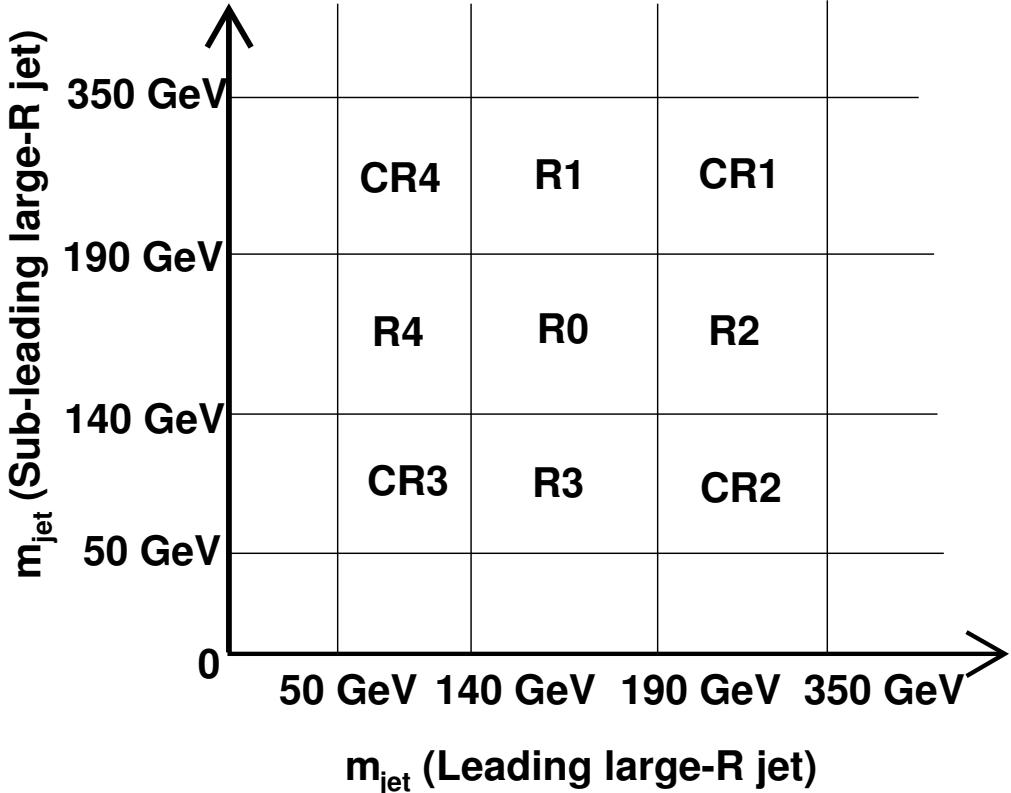

Figure 32: Event categories based on the m_{jet} .

6.3.2. τ_{32}^{wta} -likelihood ratio categories

As already mentioned in Sec. 6.2.2, events are split into further categories based on the τ_{32}^{wta} -likelihood ratio values.

- Loose : $0.35 < \tau_{32}^{wta}$ -likelihood ratio < 0.65
- Medium : $0.65 < \tau_{32}^{wta}$ -likelihood ratio < 0.8
- Tight : $0.8 < \tau_{32}^{wta}$ -likelihood ratio < 1.0

Figure 33 shows the amount of contributions from the Z' signal and the SM $t\bar{t}$ events as a function of the upper threshold on the τ_{32}^{wta} -likelihood ratio values. The lower threshold is set at 0.35. As seen in the figure, events in the R0 region with two tight b-tagged jets have the largest contributions from Z' and SM $t\bar{t}$, e.g. the contribution from Z' 1.5 TeV signal is about 10% and those of other Z' signals are below 5% at the likelihood ratio around 0.5-0.6. This is the maximum amount of the signal contamination in the lower region with low values of the τ_{32}^{wta} -likelihood ratio, which is defined as the Loose category as the validation region.

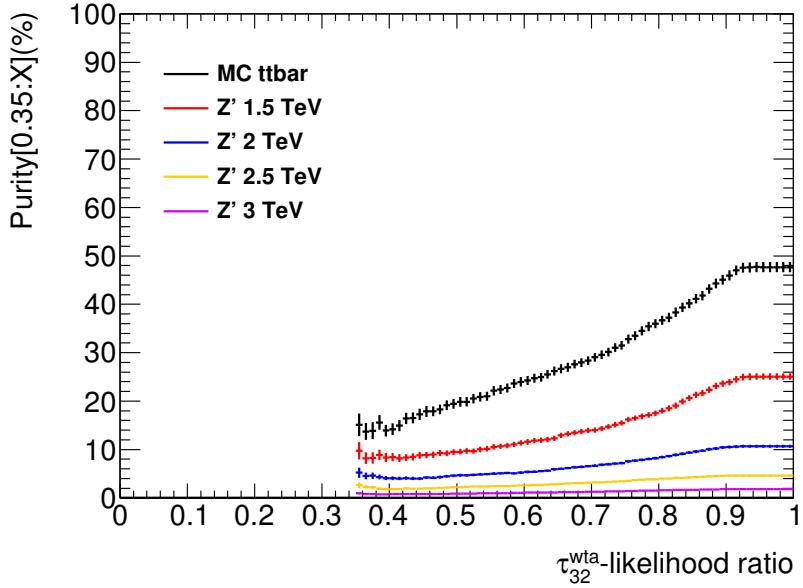

Figure 33: Scans of signal contamination (= each signal events/total background events) as a function of the upper threshold value of the τ_{32}^{wta} -likelihood ratio. The event satisfies the two tight b-tag and the mass selection of R0. The lower threshold is fixed as 0.35.

In order to define the signal region, we scan the signal sensitivity using the Z' 3 TeV signal sample by varying the lower threshold value of the τ_{32}^{wta} -likelihood ratio from 0.35 to 1.0. The upper threshold value is fixed as 1.0. The definition of the signal sensitivity used in the scan is the same as used in the earlier section, Eq. 39. The results are shown in Fig. 34. In the R0 region with two tight b-tagged jets, where the contribution of Z' events is expected to be largest, the best sensitivity is found at the value 0.8. We define the Tight category to be τ_{32}^{wta} -likelihood ratio from 0.8 to 1.0.

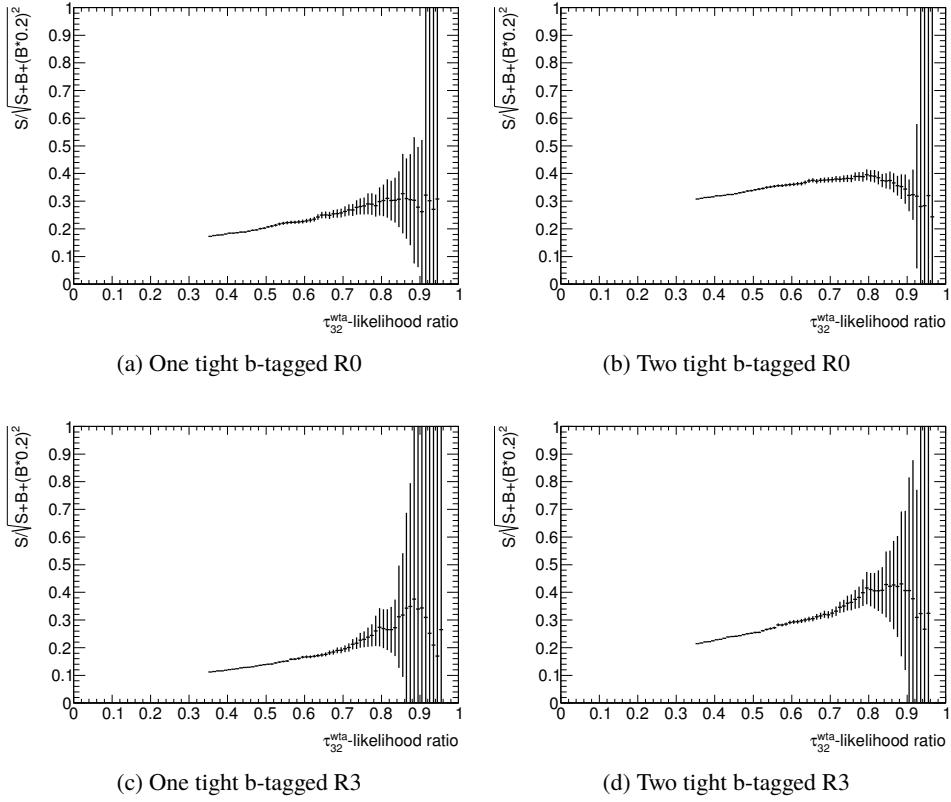

Figure 34: The signal sensitivity scans as a function of the lower threshold value of the τ_{32}^{wta} -likelihood ratio using 3 TeV Z' signal sample. The upper threshold is fixed at 1.0. Events within 2σ of $|m_{t\bar{t}} - m_{Z'}|$ are considered. They are shown for the different four regions : (a) the R0 region with one tight b-tagged jet. (b) the R0 region with two tight b-tagged jets. (c) the R3 region with one tight b-tagged jet. (d) the R3 region with two tight b-tagged jets.

The scan is repeated to define the region with the highest-sensitivity (Medium). We scan the sensitivity by changing the lower threshold value of the τ_{32}^{wta} -likelihood ratio from 0.35 to 0.8 of the τ_{32}^{wta} -likelihood ratio. The upper threshold is set at 0.8. The results are shown in Fig. 35. The best sensitivity is found at the value 0.65 in the R0 region with two tight b-tagged jets. The events with the τ_{32}^{wta} -likelihood ratio between 0.65 and 0.8 are categorized as the Medium category.

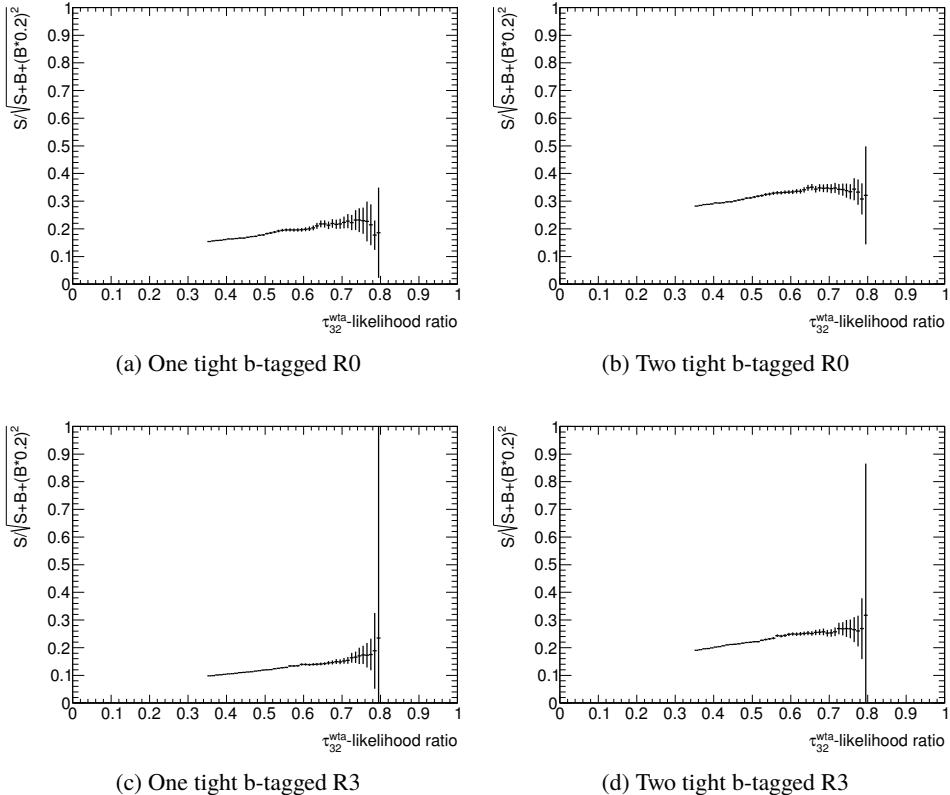

Figure 35: The signal sensitivity scans as a function of the lower threshold value of the τ_{32}^{wta} -likelihood ratio using 3 TeV Z' signal sample. The upper threshold is fixed at 0.8. Events within 2σ of $|m_{t\bar{t}} - m_{Z'}|$ are considered. They are shown for the different four regions : (a) the R0 region with one tight b-tagged jet. (b) the R0 region with two tight b-tagged jets. (c) the R3 region with one tight b-tagged jet. (d) the R3 region with two tight b-tagged jets.

We define the Loose category to have τ_{32}^{wta} -likelihood ratio from 0.35 to 0.65.

In summary, we define the Loose, Medium and Tight categories based on the values of τ_{32}^{wta} -likelihood ratio as [0.35:0.65], [0.65:0.8] and [0.8:1.0], respectively. Loose category is used to validate the background modeling and the limit extraction procedure, and Medium and Tight categories are used to extract the final cross section limits.

6.3.3. Yields and sensitivity in the event categories

Figure 36 shows the two-dimensional distributions of the leading large- R jet mass and sub-leading large- R jet mass for zero, one, and two tight b-tagged jets event categories, respectively. Figure 36 (a), (c), (e) show that most of the $t\bar{t}$ events are within the optimized large- R jet mass selection[140 GeV: 190 GeV], and small amount of events in which a top quark is partially reconstructed is seen in the lower sub-leading m_{jet} region.

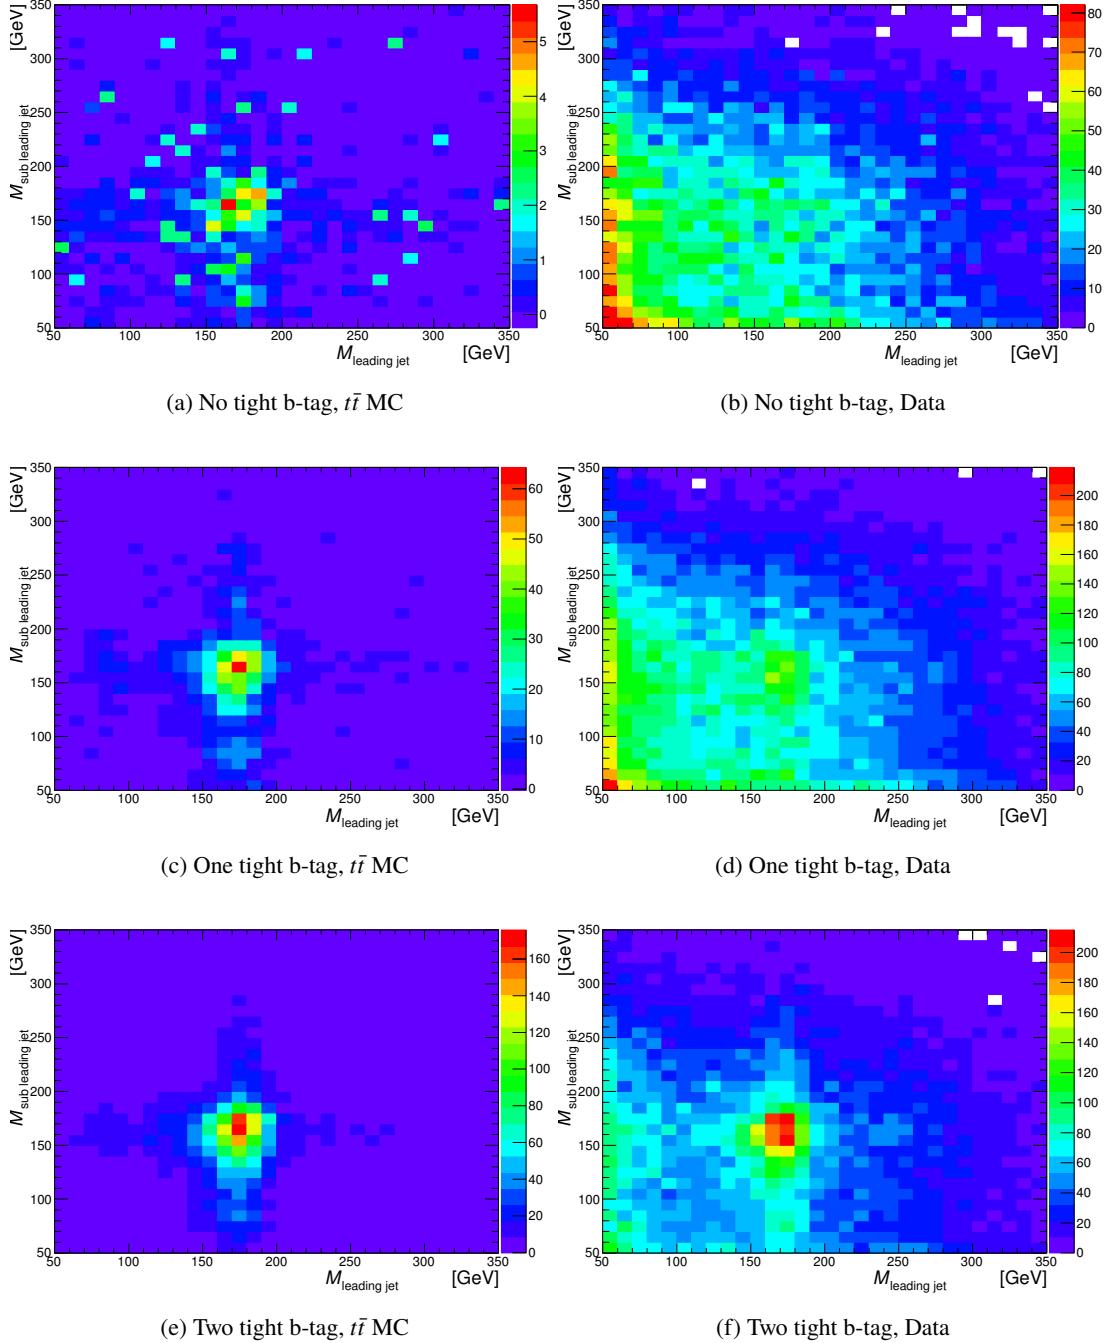

Figure 36: Two-dimensional distributions of the leading large- R jet m_{jet} and the subleading large- R jet m_{jet} , Shown separately for each b-tag categories. (a), (c), (e) are for the SM $t\bar{t}$ sample and (b), (d), (f) are for data. The m_{jet} categorisation and τ_{32}^{wta} categorisation not applied.

The definition of the categories (regions) are summarized in Fig. 37. The m_{jet} sideband region is defined as the control region (CR), where the multi-jet events are dominant while the contribution from the SM $t\bar{t}$ events is relatively small. This region is used to normalize the QCD multijet background while the shape is extracted from 0 b-tagged events in each region.

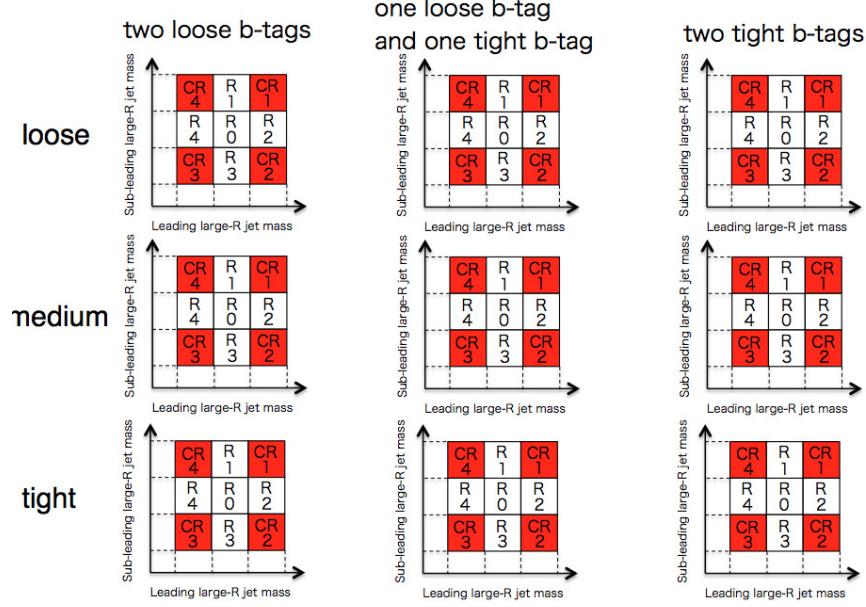

Figure 37: Definition of regions

Signal and background yields around signal mass points (Z' 1.5 TeV and Z' 3 TeV) in each region are checked and the sensitivity in each region is estimated. They are summarised in Table. 8, 9. Each sensitivity is also shown. As seen in the tables, the Loose region has lower sensitivity. The R0 and R3 regions have higher sensitivities compared to other regions. In the region R0, the selected two jets are both consistent with the top quark mass. In the region R1, the selected leading jet is consistent with the top quark mass while the sub-leading jet is not but still contains major amount of decay objects from the top quark.

Regions	$t\bar{t}$	Data Driven QCD	Total BG	$Z' 1.5 \text{ TeV}$	$\frac{S}{\sqrt{S+B}}$	S/B

Table 9: Event yields and the sensitivity to the $Z' 3 \text{ TeV}$ sample in each region. Events within 2σ from $m_{Z'} = 3 \text{ TeV}$ are considered as the signal.

Signal region, template control region and validation region are defined as described in Fig. 38.

The template region (TR) is defined to obtain multi-jet background templates. Details of multi-jet background estimation is written in Sec. 7.2.

As already mentioned, R0 and R3 have high sensitivity to the signal. In order to simplify the analysis, only R0 and R3 are used to obtain the final cross section limits. Table 10 and Fig. 39 show the comparisons of the expected limits between the results using the R0+R3 Medium and Tight region and those using R0+1+2+3+4 Medium and Tight. The reduction of sensitivity using the R0-4 regions is about 4.8% for the $t\bar{t}$ mass point of 3 TeV.

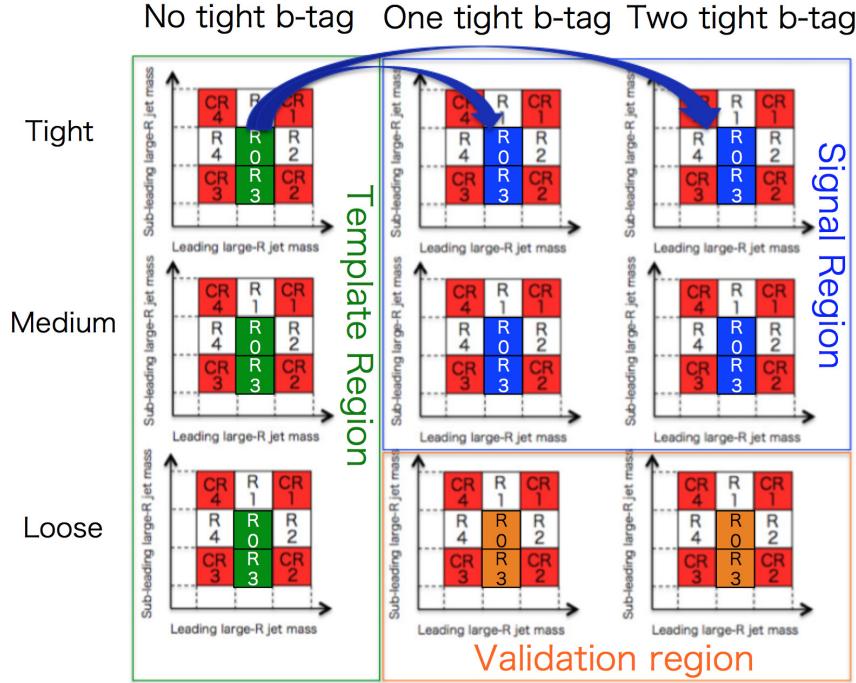

Figure 38: Definition of template region, control region and validation region.

Mass Points (TeV)	1	1.25	1.5	1.75	2	2.25	2.5	2.75	3	4	5

Table 10: Expected cross-section limits for each Z' mass point using different regions. Residual means ($(R0+1+2+3+4) - (R0+R3)$) / $(R0+R3)$.

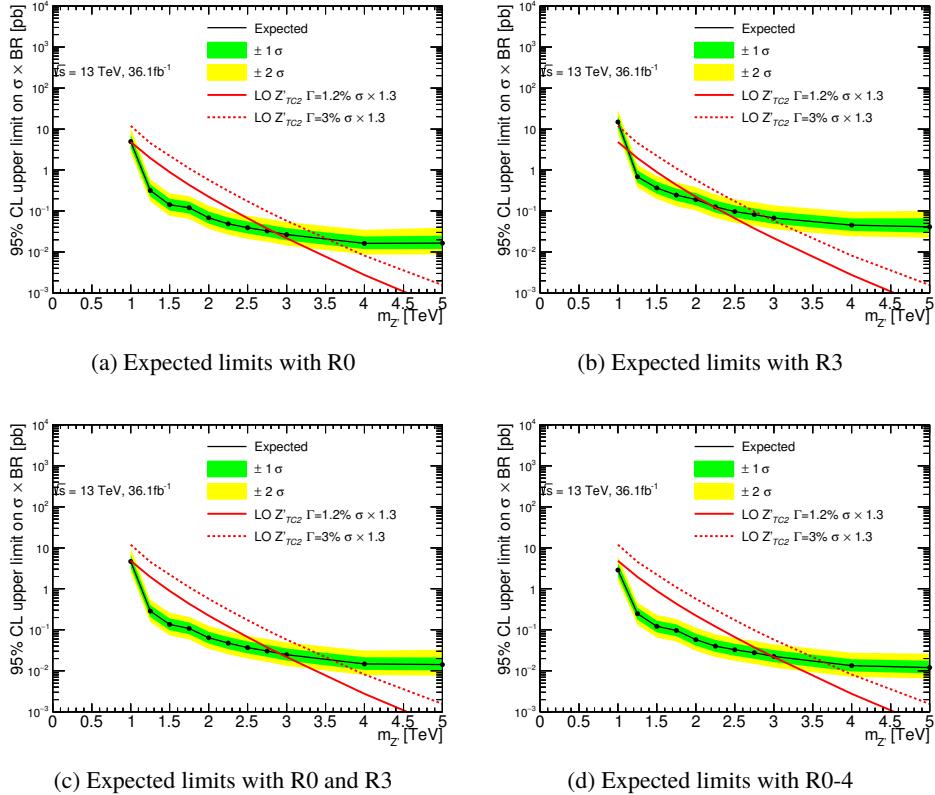

Figure 39: Expected limits R0 and R3, and of all R0-4 regions. All systematic uncertainties are considered in the estimation. Black line shows expected 95% confidence level (CL) upper limit on cross section times branching ratio (pb). Green (Yellow) band shows $\pm 1\sigma$ ($\pm 2\sigma$) band for the expected limit. Red solid (dash) line shows theoretical expectation of Z' with 1.2% (3%) width of $m_{t\bar{t}}$. Details of using calculation is described in Sec. 9

7. Background Estimation

QCD multijet events and the Standard Model $t\bar{t}$ events are considered as backgrounds in this analysis. Other contributions (Single top Wt channel, W+Jets, Z+Jets and top pair production associated with W) are also checked and found to be negligible as can be seen in Table 11.

Table 11: Background yields and ratio

7.1. Standard Model $t\bar{t}$ background

The background due to the Standard Model production of $t\bar{t}$ events is estimated directly from Monte Carlo simulation, generated with the PowHEG generator and PYTHIA for the parton shower. For a more precise estimate of this background at very high mass region, $m_{t\bar{t}}$ -sliced samples are being used in this analysis.

Comparing the $m_{t\bar{t}}$ distributions for the three τ_{32}^{wta} -likelihood categories (Loose, Medium and Tight), as can be seen in Fig. 40, shows that they are all consistent with each other. Therefore, the three are all merged to have more statistics for a better determination of the $m_{t\bar{t}}$ distribution for the SM $t\bar{t}$ background. We also checked difference of $m_{t\bar{t}}$ distributions between the two different b-tagging categories, as can be seen in Fig. 41, it is found that their distributions are different because of the difference of b-tagging efficiency drop at high p_T , therefore we don't merge the distributions of one tight b-tagged events and two tight b-tagged events, and they are to be dealt with separately for the estimation of the Standard Model $t\bar{t}$ background.

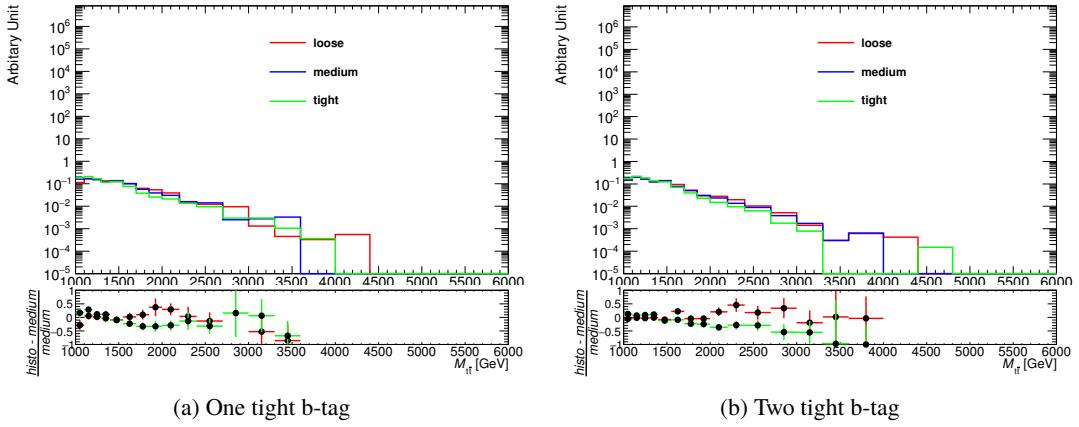

Figure 40: Distributions of the $m_{t\bar{t}}$ in the signal region with the three τ_{32}^{wta} -likelihood categories in SM $t\bar{t}$ Monte Carlo sample.

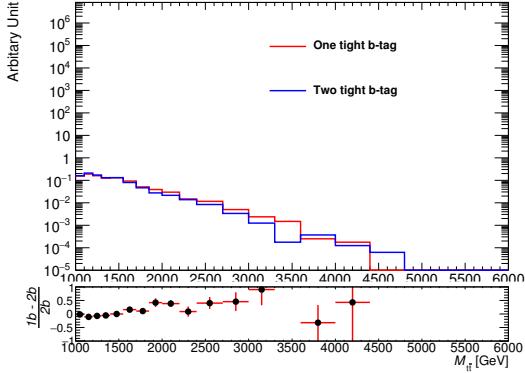

Figure 41: Distributions of the $m_{t\bar{t}}$ in the signal region with the two b-tagging categories in SM $t\bar{t}$ Monte Carlo sample. The three τ_{32}^{wta} -likelihood categories are merged.

7.2. QCD multijet background

The QCD multijet background is estimated from data with the help of Monte Carlo samples.

The shape of the $m_{t\bar{t}}$ distribution of the QCD multijet background is determined from events where no tight b-tagged track jets are found while other selections are passed. This region is defined as the 'template region' or 'TR' in Sec. 6.3.3. The template yields and $t\bar{t}$ purity in each template region are summarized in the Table 12. $t\bar{t}$ purity is sufficiently low, and the TRs can be used to obtain the shape of multijet from data suppressed the contributions of the MC $t\bar{t}$.

Table 12: Template yields and $t\bar{t}$ purity in each multijet template region (no tight b-tag). Templates are obtained by data subtracted MC $t\bar{t}$

Region	Loose R0	Loose R1	Loose R2	Loose R3	Loose R4
Yields	1823.08 ± 43.23	2100.75 ± 46.06	2225.62 ± 47.47	4859.19 ± 70.12	5869.97 ± 76.88
$t\bar{t}$ purity(%)	1.67 ± 0.21	0.63 ± 0.132	0.64 ± 0.165	0.83 ± 0.08	0.48 ± 0.062
Region	Medium R0	Medium R1	Medium R2	Medium R3	Medium R4
Yields	532.55 ± 23.87	724.39 ± 27.29	816.81 ± 28.86	1143.07 ± 34.26	1456.62 ± 38.45
$t\bar{t}$ purity(%)	4.90 ± 0.60	1.58 ± 0.41	1.35 ± 0.27	1.80 ± 0.27	0.98 ± 0.18
Region	Tight R0	Tight R1	Tight R2	Tight R3	Tight R4
Yields	203.25 ± 15.90	313.89 ± 18.36	344.66 ± 19.14	298.28 ± 17.94	446.65 ± 21.51
$t\bar{t}$ purity(%)	14.96 ± 1.836	4.01 ± 0.99	3.73 ± 0.839	5.31 ± 0.89	2.26 ± 0.53

In order to reduce the statistical uncertainty of the shape extraction, τ_{32}^{wta} -likelihood categories (Loose, Medium, Tight) are merged, after checking shape consistency of $m_{t\bar{t}}$ distributions, as can be found in Fig. 42.

The normalization of the QCD multijet background is estimated from the number of events in the template region multiplied by the ratio between events with no tight b-tagged jets and events with two tight b-tagged jets (or one tight b-tagged jets) in control regions (as defined below). This ratio is called the 'normalization factor'.

The contamination from Standard Model $t\bar{t}$ events in the QCD control regions is also checked and summarized in Table 13. This contamination from the Standard Model $t\bar{t}$ events is subtracted using Monte Carlo simulation in the QCD multijet background estimation.

The normalization factor n_{category} is estimated from a simple average of the four control regions (Eq. (40)),

$$n_{\text{category}} = \frac{n_{\text{CR1,category}} + n_{\text{CR2,category}} + n_{\text{CR3,category}} + n_{\text{CR4,category}}}{4} \quad (40)$$

after checking their consistency. The resulting normalization factors are summarized in Fig. 43 and Table 14.

Distributions of the $m_{t\bar{t}}$ for tight b-tagged events and no tight b-tagged events are compared in the control region, and small difference is found as can be seen in Fig. 44. This difference is corrected by using a correction function ($p_0/x + p_1 \times x + p_2$) as a function of scalar sum of jet p_T 's ($p_{T(jet1)} + p_{T(jet2)}$) estimated from QCD multijet Monte Carlo simulation, as shown in ratio between two tight b-tagged events and zero tight b-tagged events in Fig. 45. In order to reduce the statistical uncertainty of the extraction of the correction function, τ_{32}^{wta} -likelihood categories (Loose, Medium, Tight) are merged for this extraction, after checking shape consistency for various distributions (See Appendix E).

The correction function for data is also checked, and it is found to be consistent. Figure 47 shows the distribution of the $m_{t\bar{t}}$ in the control region for no b-tagged region after the correction and b-tagged region. The corrected no b-tagged distributions agree well with that for tight b-tagged events. Figure 46 shows the ratio of the $m_{t\bar{t}}$ between one or two tight b-tagged events and no tight b-tagged events before and after the shape correction. Those ratios become flat after the shape correction.

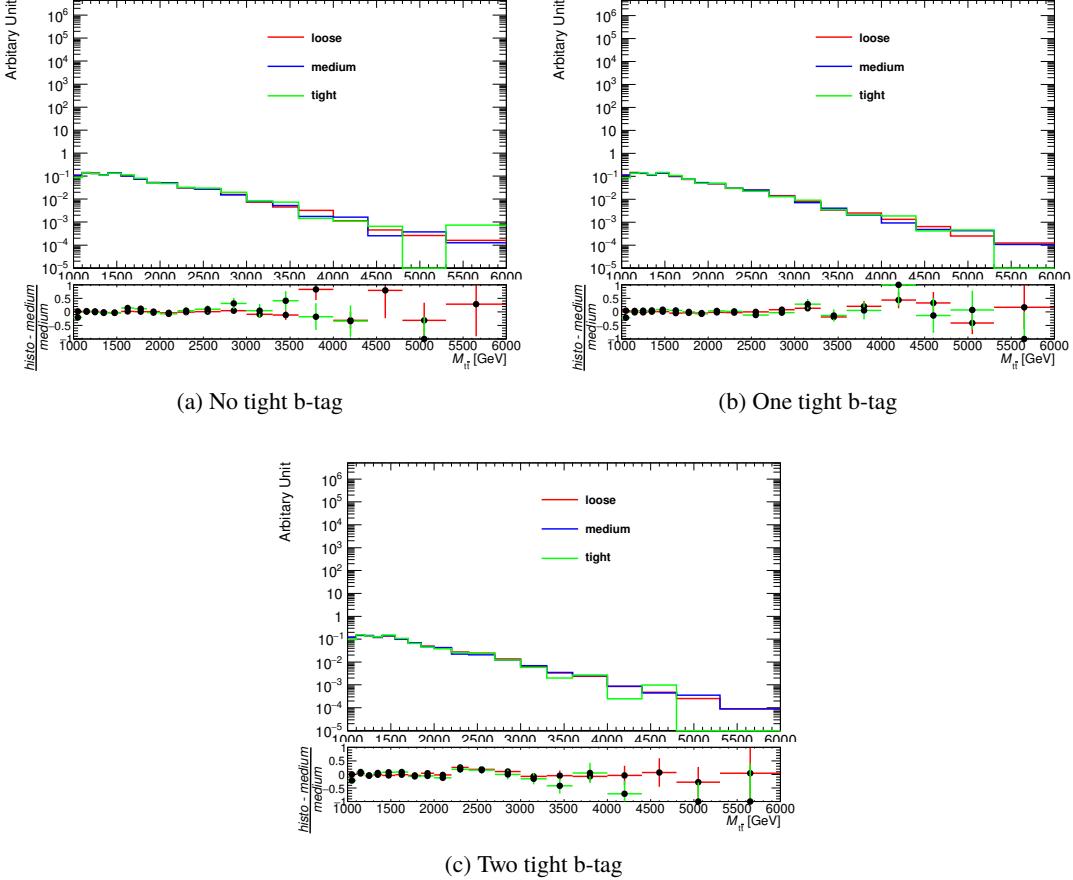

Figure 42: Distributions of the $m_{t\bar{t}}$ for the QCD multijet background (Data subtracted $t\bar{t}$ contributions with MC $t\bar{t}$) with several τ_{32}^{wta} -likelihood categories in control region (CR1+CR2+CR3+CR4).

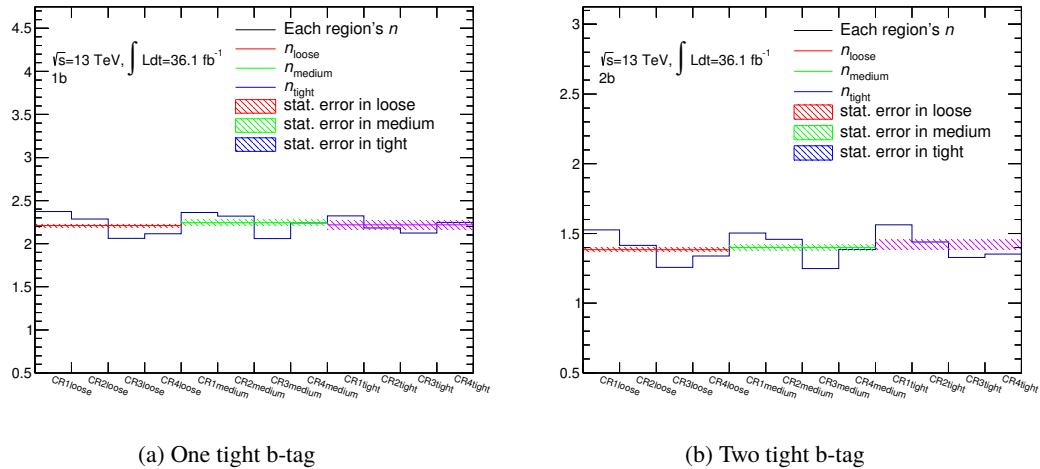

Figure 43: Normalization factors in each control region, and the averaged values.

Table 13: Contamination from the Standard Model $t\bar{t}$ events in the QCD control regions.

7.3. Extrapolation to the high $m_{t\bar{t}}$ region

Given the limited size of the samples being used by this analysis, the background estimation at very high mass region, $m_{t\bar{t}} > 2.5$ TeV, is not that accurate as can be seen in Fig. 48. We perform a fitting of the $m_{t\bar{t}}$ distribution using an exponential function ($\exp(p_0 + p_1 \times x)$) to estimate the $m_{t\bar{t}}$ distribution in high mass region.

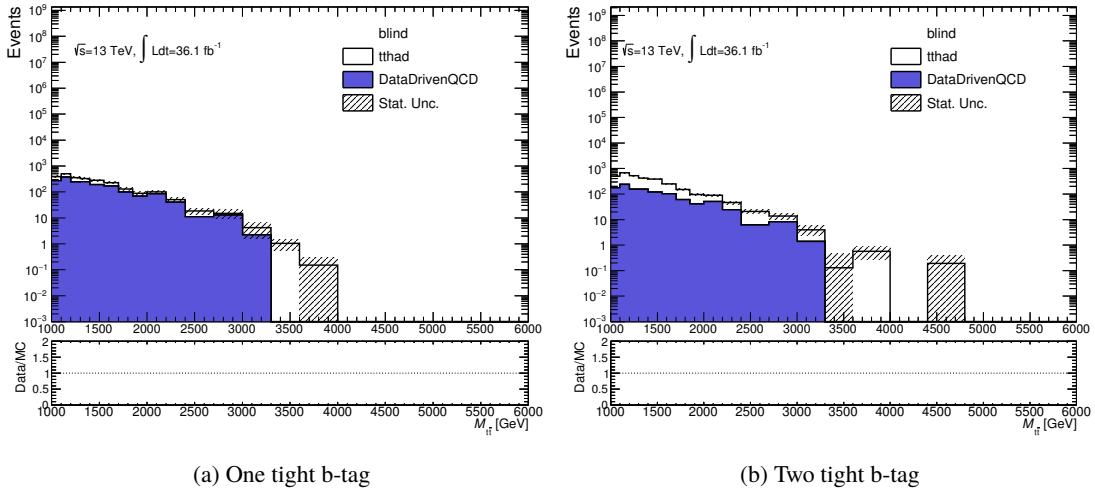

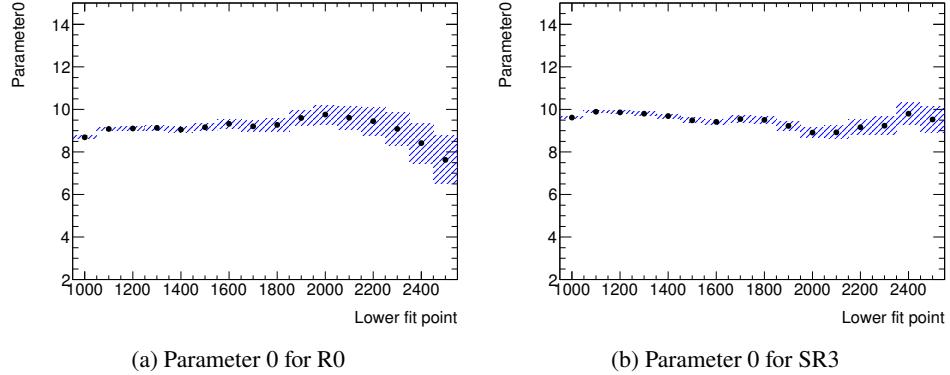

Figure 48: Distributions of the $m_{t\bar{t}}$ in the signal region (data blinded). τ_{32}^{wta} -likelihood categories are merged.

The fit range is determined by checking the slope parameter of the fit varying the fit range from certain lower $m_{t\bar{t}}$ point to $m_{t\bar{t}} = 4$ TeV. Figure 49 shows the scan result of the parameter p_0 , varying the fit starting point for the QCD multijet template in R0,R3,VR0 and VR3. From this result, any lower edges from 1.2 TeV to 2 TeV can be used for the multijet sample, where the slope parameter is stable and the size of the uncertainty is reasonably small. We do not this exponential extrapolation from the lowest edge of the histogram 1 TeV, because there is a strong bias from turn-on of the $m_{t\bar{t}}$ distribution due to kinematical selections. We choose 1.2 TeV as the lower edge of the exponential fit, and use 1.5 TeV as the start point of the exponential extrapolation for the multijet background. We use the original histograms before 1.5 TeV, because the region less than 1.5 TeV has sufficient statistics and it is better that the raw histogram shape is kept in this region. Figure 50 shows the scan result of the parameter p_1 , varying the fit starting point for the QCD multijet template in R0,R3,VR0 and VR3. The parameter 1 is not widely moved in comparison of parameter 0.

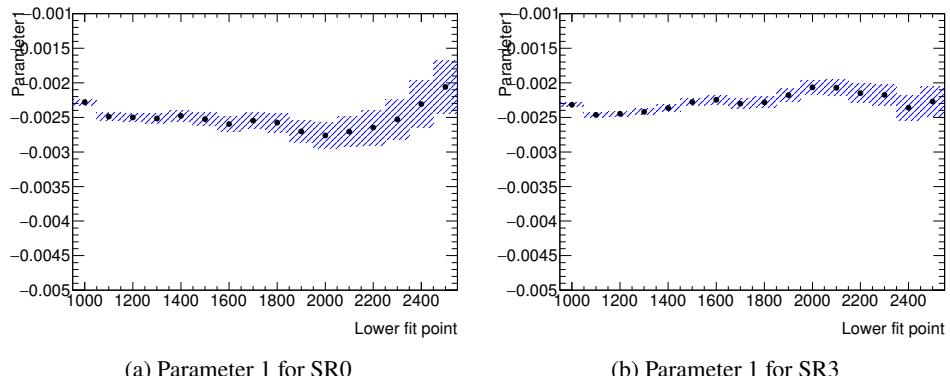

Figure 51 and 52 show similar results for the Standard Model $t\bar{t}$ all-hadronic events. For $t\bar{t}$ background, the extrapolation is performed to inclusive distribution. Inclusive means that all-hadronic channel and semi-leptonic channel are combined. The size of this background is very small, a few % level compared to the all-hadronic $t\bar{t}$ events in the signal region. From this result, any lower edges from 1.2 TeV to 2 TeV can be used for the SM $t\bar{t}$ background. We choose 1.2 TeV as the lower edge of the exponential fit, and use 1.5 TeV as the start point of the exponential extrapolation for the SM $t\bar{t}$ background.

(a) Parameter 0 for R0

(b) Parameter 0 for SR3

Figure 49: Slope parameter of the exponential $m_{t\bar{t}}$ fit, varying fitting lower edge for QCD multijet background for two tight b-tagged category, and one tight b-tagged category is also similar because of using a common template shape.

(a) Parameter 1 for SR0

(b) Parameter 1 for SR3

Figure 50: Constat parameter of the exponential $m_{t\bar{t}}$ fit, varying fitting lower edge for QCD multijet background for two tight b-tagged category, and one tight b-tagged category is also similar because of using a common template shape.

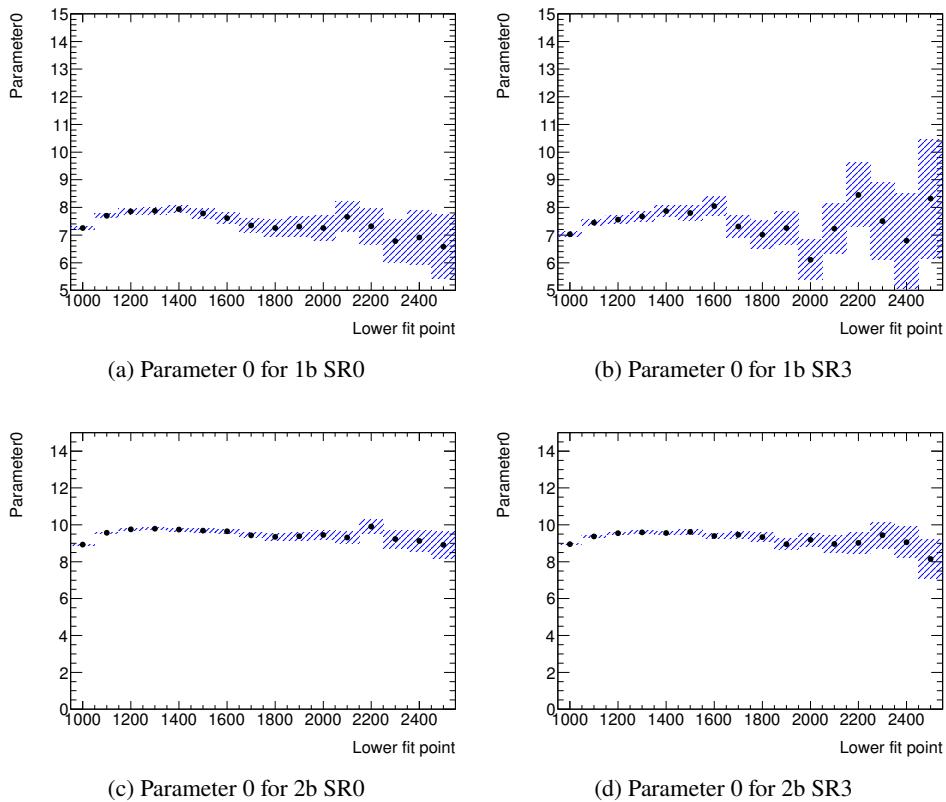

Figure 51: Slope parameter of the exponential $m_{t\bar{t}}$ fit, varying fitting lower edge for the Standard Model $t\bar{t}$ background.

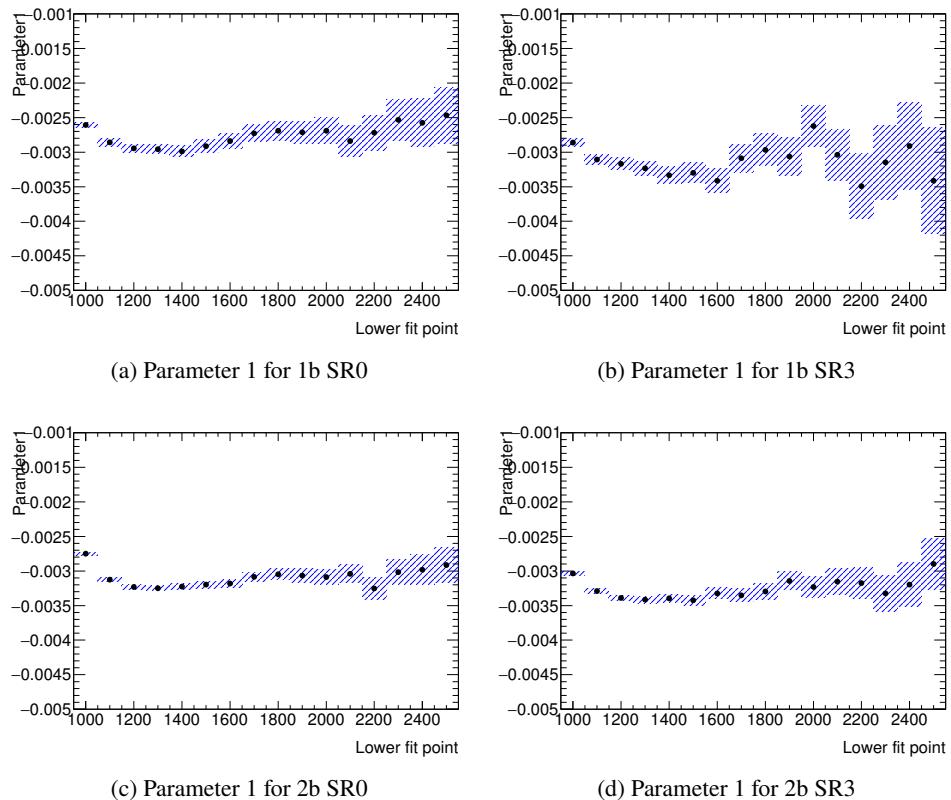

Figure 52: Constat parameter of the exponential $m_{t\bar{t}}$ fit, varying fitting lower edge for the Standard Model $t\bar{t}$ background.

Systematic uncertainty on this extrapolation method includes statistical uncertainty of the fit, and stability of the fit range choice. Stability of the fit range choice is evaluated by taking the maximum deviation from the nominal slope parameter when changing the lower edge of the fit range, until the statistical fluctuation becomes large, as can be seen from Fig. 49 for the QCD multijet background, and Fig. 51 for the SM $t\bar{t}$ background.

We take the difference of the exponential fit results between when we use 1.2 TeV as the lower edge of the fit and when we use 1.7 TeV as the lower edge of the fit, as a systematic uncertainty. The statistical uncertainty in the lower $m_{t\bar{t}}$ region is low, therefore lower fit point decide the precision of fit. In addition, region of $m_{t\bar{t}}$ which has sufficient events is limited from 1.2 TeV to 4 TeV. Hence, we keep higher fit point 4 TeV, and only check the variation of the lower fit point. Exactly, there is the way of using alternative function to estimate systematics, but it is hard to check if fit is successful or not, because we have many regions. Therefore current method is the simplest and can be easily treated.

An alternative function, di-jet mass function ($p_0 \times (1 - \frac{x}{\sqrt{s}})^{P_1} \times (\frac{x}{\sqrt{s}})^{P_2}$), is also tried, and it is observed that the extrapolated shapes are consistent with the nominal function (exponential) within the statistical uncertainty.

8. Systematic Uncertainties

We describe the details of all systematic uncertainties considered in this analysis. In the Loose, Medium, and Tight region, all systematic uncertainties of $t\bar{t}$ and multi-jet background are estimated from merged distributions (Loose+Medium+Tight). Systematic uncertainties are consistent between each τ_{32}^{WTA} -likelihood category, therefore only systematic plots in the Tight region are shown here.

Systematic uncertainties for the SM $t\bar{t}$ are estimated by fitting the difference between the systematic sample and nominal sample with a linear function in order to reduce the statistical jumps due to the limited sample statistics, and the systematic uncertainty for the shape correction for the multi-jet background is also estimated by the same way. We checked alternative method, using original ratio distributions with merged bins instead of using the linear fit, and found reasonable results and it does not change the final results as can be found Appendix A

8.1. Systematic uncertainty on integrated luminosity

The combined luminosity error for 2015 and 2016 is 2.1%, assuming fully uncorrelated uncertainties in 2015 and 2016. It is applied as a constant shift to signal and SM $t\bar{t}$ backgrounds.

8.2. Systematic uncertainty on b-tagging of the track-jets

The prescription for implementing the b -tagging uncertainty recommended by the performance group has been followed. The eigenvector breakdown approach has been tested to avoid over-profiling. There are 4 (4 and 11) eigenvectors for the b -flavor (c - and light-flavor) quarks, and 2 eigenvectors specifically for the extrapolation of the scale factor in high p_T regimes, which are correlated across the flavors.

Nominal $m_{t\bar{t}}$ distribution and systematic varied distributions are shown in Fig. 53 for the SM $t\bar{t}$ background, Fig. 54 for Z' . Bottom distributions are the differences between nominal and systematic varied distributions in those plots.

8.3. Systematic uncertainty on large- R jet

The scale uncertainties on the large- R jets (which is propagated to the top-tagging performance) are estimated using the r_{trk} method. The method assumes that the tracking device-related uncertainties are uncorrelated with the calorimeter cluster-related uncertainties. The procedure works by estimating the ratio r_{trk} between an observable (which can be the transverse momentum, mass or a substructure quantity) calorimeter-jet and a track-jet, which have been matched to be in the same detector region. Such ratio is estimated in both data and in simulation and the deviation of the average double ratio $\langle R_{trk} \rangle = \frac{\langle r_{trk}^{\text{data}} \rangle}{\langle r_{trk}^{\text{MC}} \rangle}$ from 1 is used as a figure of merit to quantify the uncertainty. In addition, a track measurement uncertainty is estimated and added in quadrature.

The large- R jet uncertainty is broken down into 4 components: “baseline”, which refers to the difference between data and the PYTHIA 8 simulation; “modelling”, which refers to the difference between data and the Herwig simulation; “tracking”, which refers to the uncertainty on the tracks used as a reference; and the statistical uncertainty. Different configurations of uncertainties are available, depending on whether one assumes the p_T , mass and τ_{32}^{wta} observables to be correlated or not. This analysis uses the “strong” configuration, on which all observables are assumed to be correlated, since the signal region is rather pure in the $t\bar{t}$ background.

Nominal $m_{t\bar{t}}$ distribution and systematic varied distributions for large- R jet baseline uncertainty are shown in Fig. 59 for the SM $t\bar{t}$ background, Fig. 60 for Z' . Bottom distributions are the differences between nominal and systematic varied distributions in those plots.

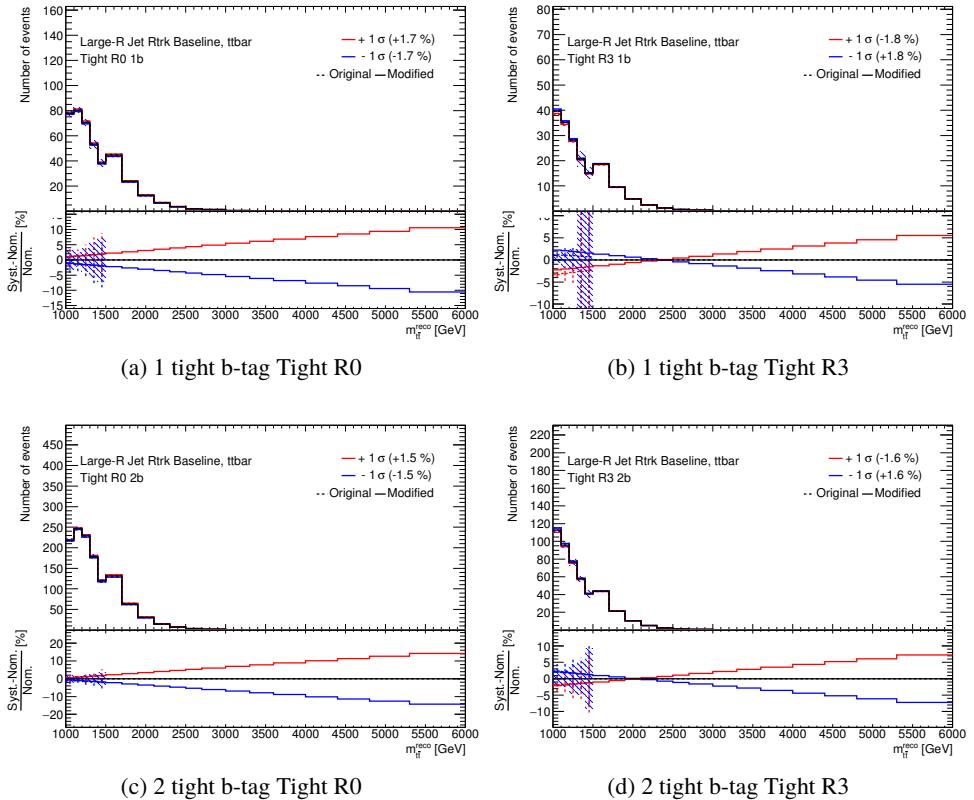

Figure 59: Systematics of “baseline” for the SM $t\bar{t}$ background

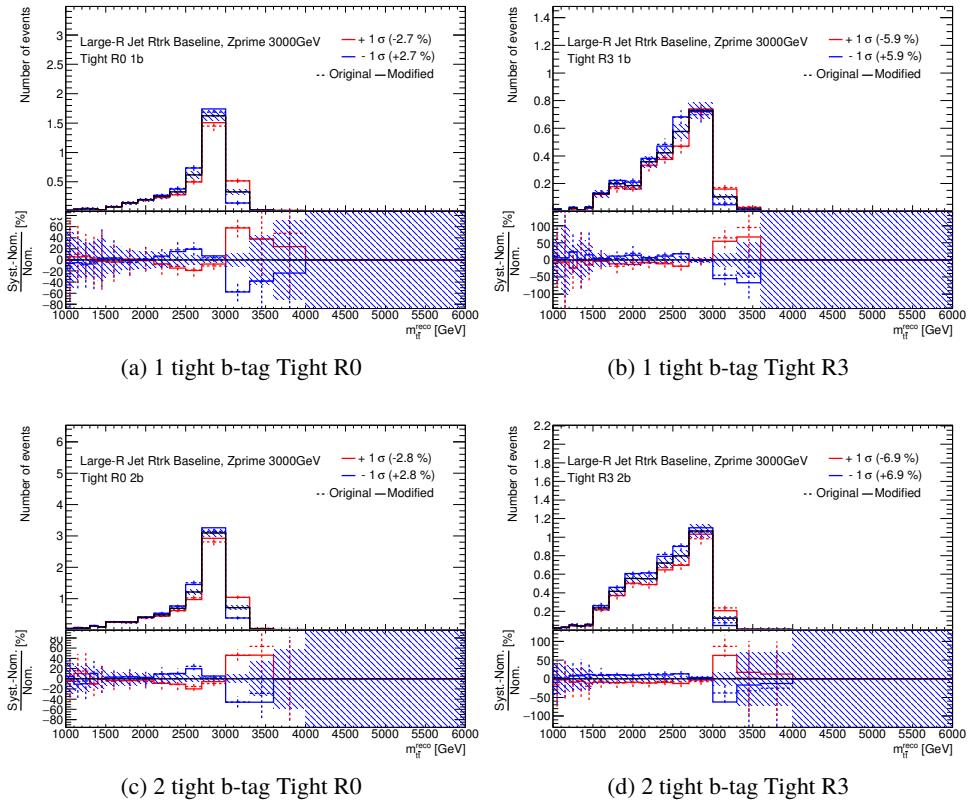

Figure 60: Systematics of “baseline” for Z' 3 TeV

Nominal $m_{t\bar{t}}$ distribution and systematic varied distributions for large-R jet model uncertainty are shown in Fig. 61 for the SM $t\bar{t}$ background, Fig. 62 for Z' . Bottom distributions are the differences between nominal and systematic varied distributions in those plots.

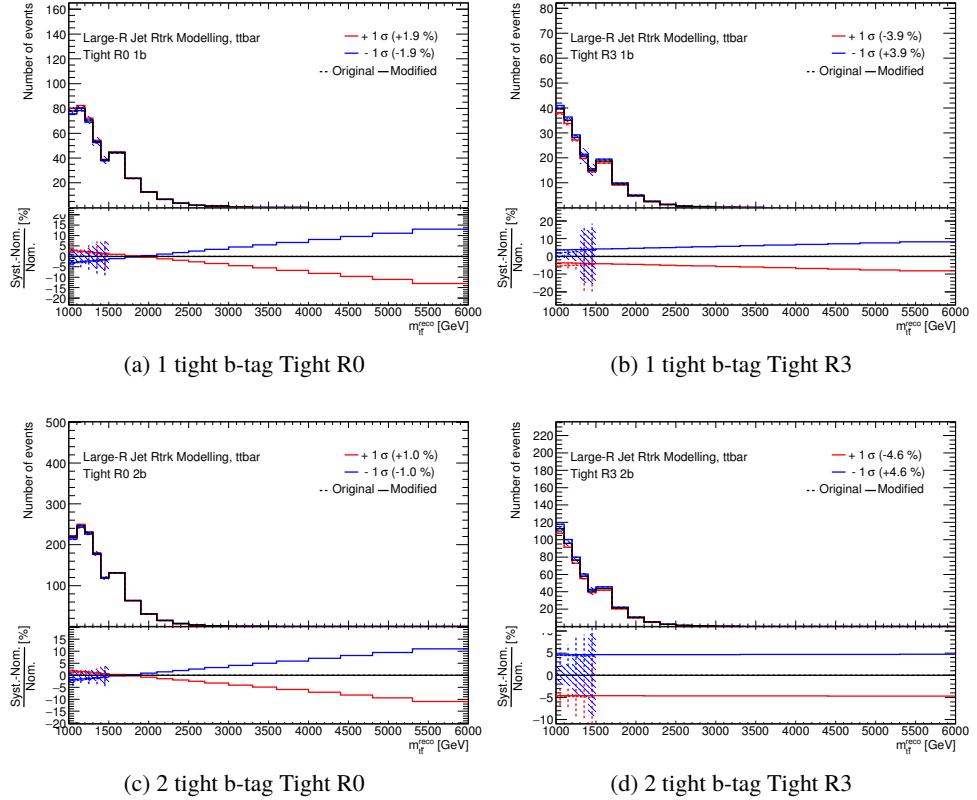

Figure 61: Systematics of “modelling” for the SM $t\bar{t}$ background

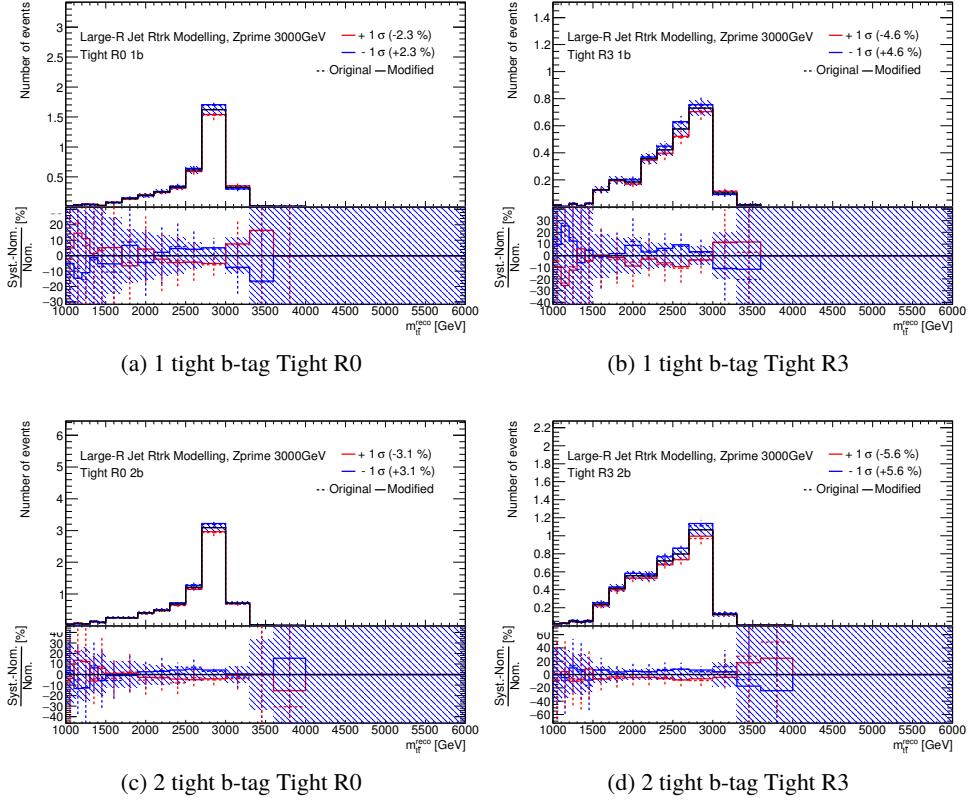

Figure 62: Systematics of “modelling” for Z' 3 TeV

Nominal $m_{t\bar{t}}$ distribution and systematic varied distributions for large-R jet track uncertainty are shown in Fig. 63 for the SM $t\bar{t}$ background, Fig. 64 for Z' . Bottom distributions are the differences between nominal and systematic varied distributions in those plots.

Nominal $m_{t\bar{t}}$ distribution and systematic varied distributions for large-R jet statistics uncertainty are shown in Fig. 65 for the SM $t\bar{t}$ background, Fig. 66 for Z' . Bottom distributions are the differences between nominal and systematic varied distributions in those plots.

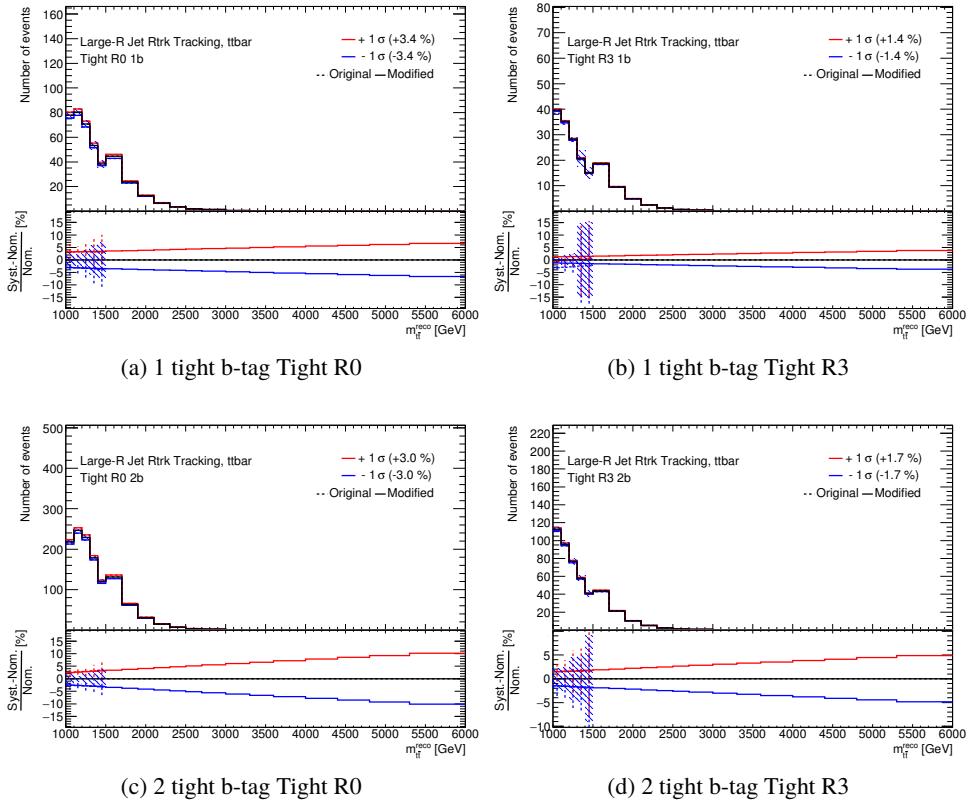

Figure 63: Systematics of “tracking” for the SM $t\bar{t}$ background

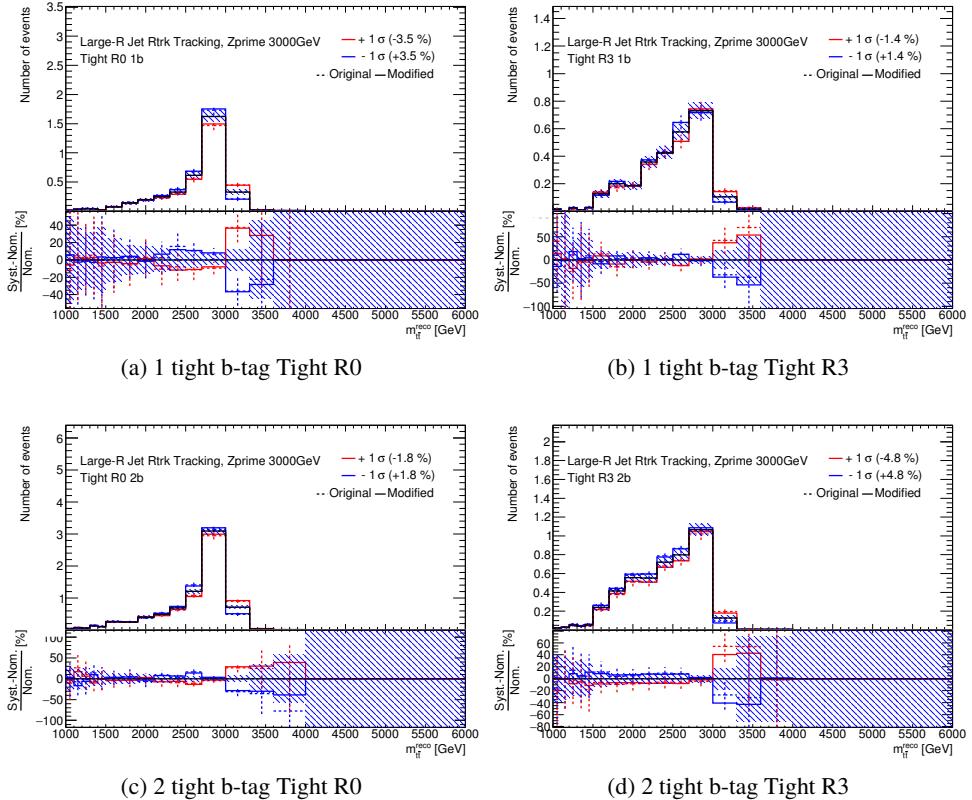

Figure 64: Systematics of “tracking” for Z' 3 TeV

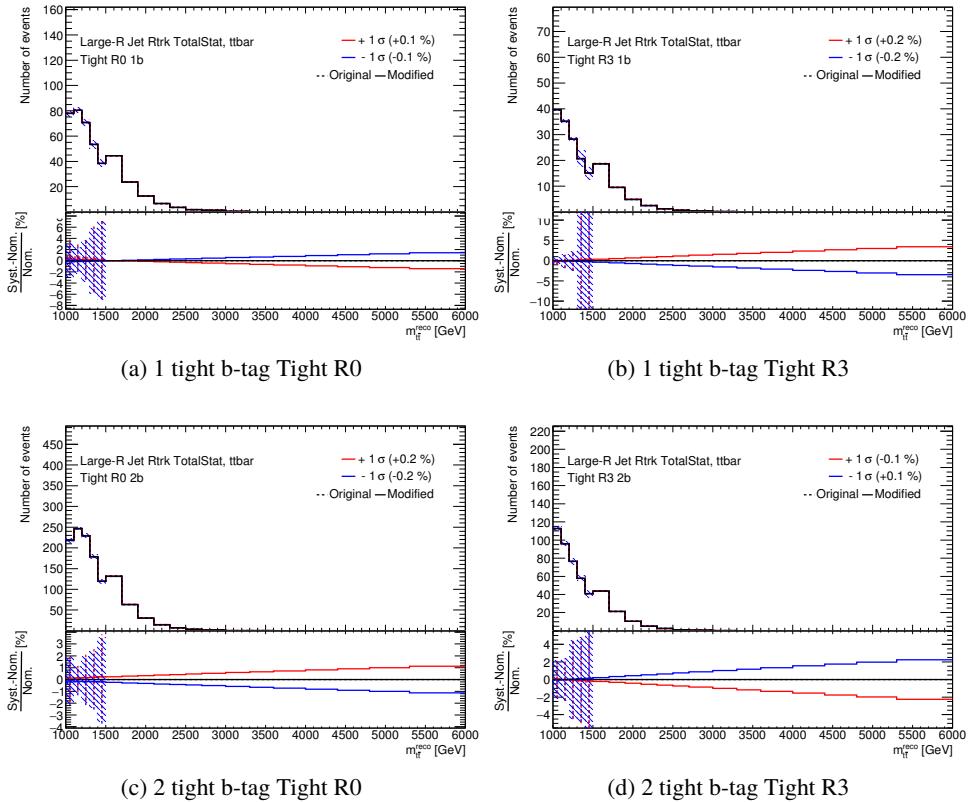

Figure 65: Systematics of ‘Statistical’ for the SM $t\bar{t}$ background

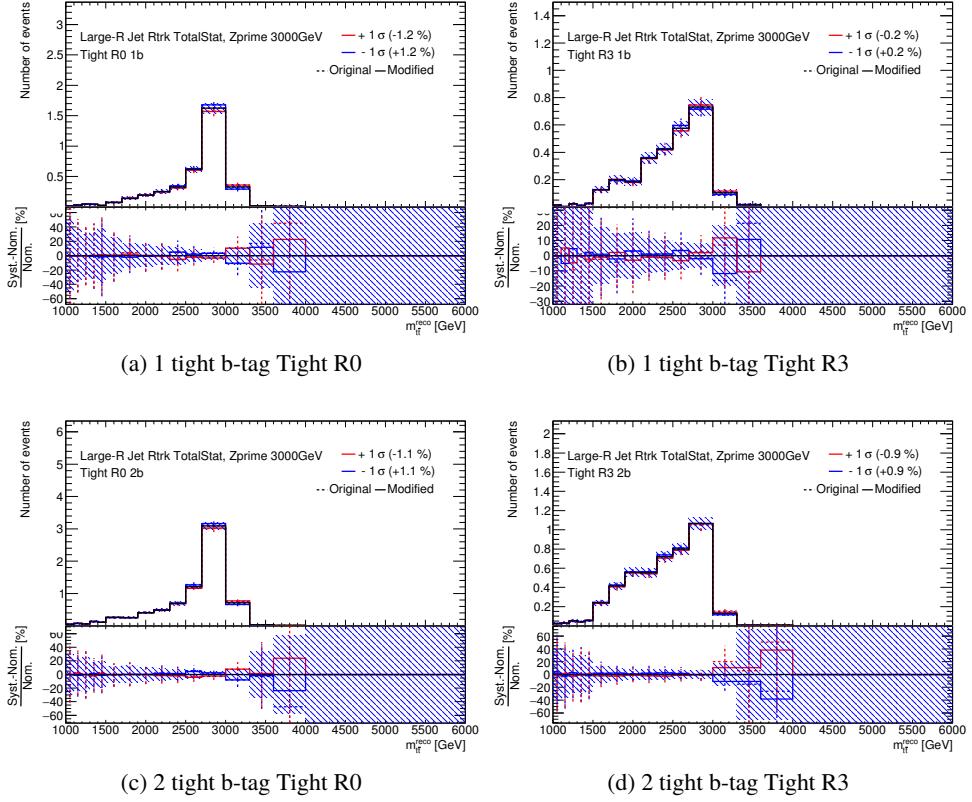

Figure 66: Systematics of “Statistical” for Z' 3 TeV

In addition, some differences for resolution of large- R jet can be seen between data and MC. The differences are estimated for large- R jet p_T (2%), mass (20%) and τ_{32}^{wta} (15%).

The value for large- R jet p_T is absolute value. The values for large- R jet mass and τ_{32}^{wta} are relative value to each resolution simulated by MC, $\sigma_{nominal}$. If σ_{NEW} is defined as a resolution after smearing by a Gaussian with recommended value, σ_{NEW} is related to $\sigma_{nominal}$ as a Eq. (41).

$$\sigma_{NEW}^2 = \sigma_{nominal}^2 + (x \cdot \sigma_{nominal})^2 \quad (41)$$

$x \cdot \sigma_{nominal}$ is used to smearing for mass and τ_{32}^{wta} . For example, σ_{NEW} is equal to $1.2\sigma_{nominal}$ for mass, therefore x can be calculated. Each uncertainty is estimated by smearing p_T by a Gaussian with a width of 2%, smearing mass by a Gaussian with a width of $0.66\sigma_{nominal}$ and smearing τ_{32}^{wta} by a Gaussian a width of $0.57\sigma_{nominal}$, respectively. Each $\sigma_{nominal}$ is estimated by inter quantile range (IQR) as Fig. 67. p_T dependency is small, and η dependency also small in Fig. 68.

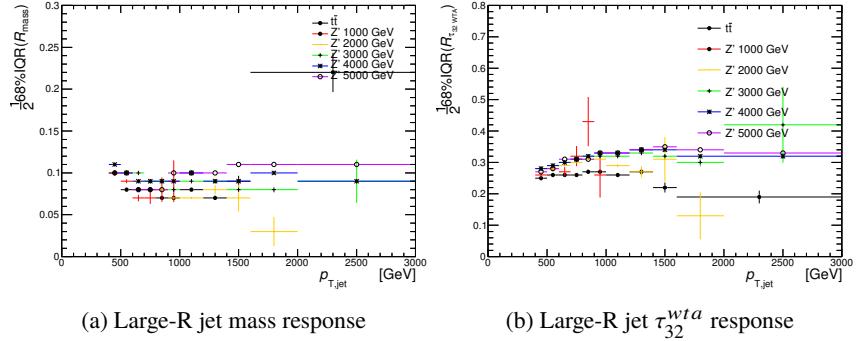

Figure 67: Response of large- R jet kinematics

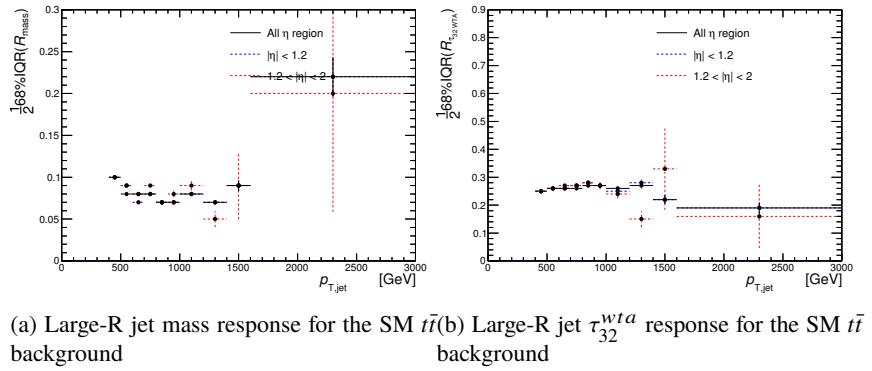

Figure 68: Check η dependency for response of large- R jet kinematics

Each smeared distribution is showed in Fig. 69.

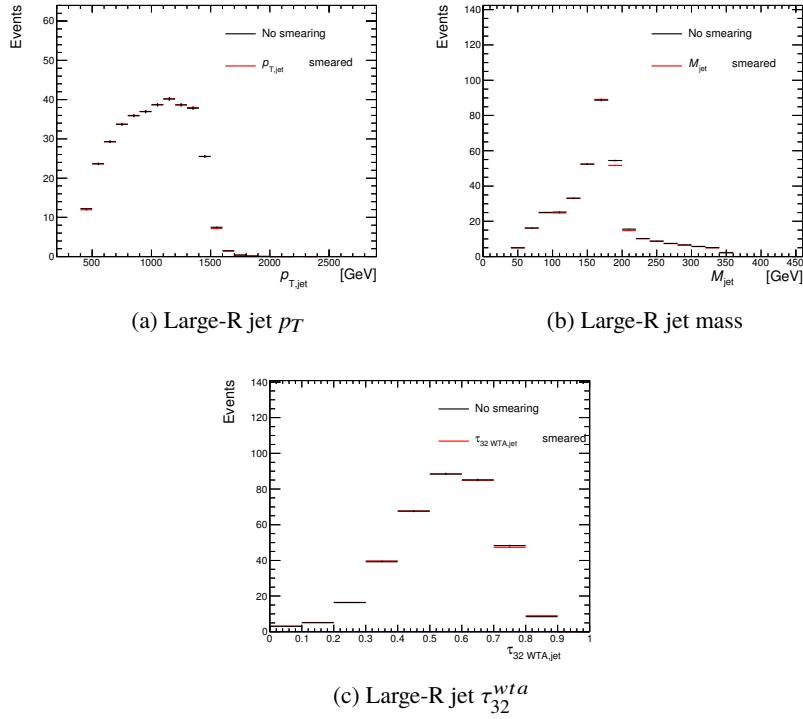

Figure 69: Smeared distribution for Z' 3 TeV

Each systematic uncertainty is estimated by using same event selection with smeared value.
The results are showed in $m_{t\bar{t}}$ distribution(Figure 70, 71 and 72 and Figure 73, 74 and 75).

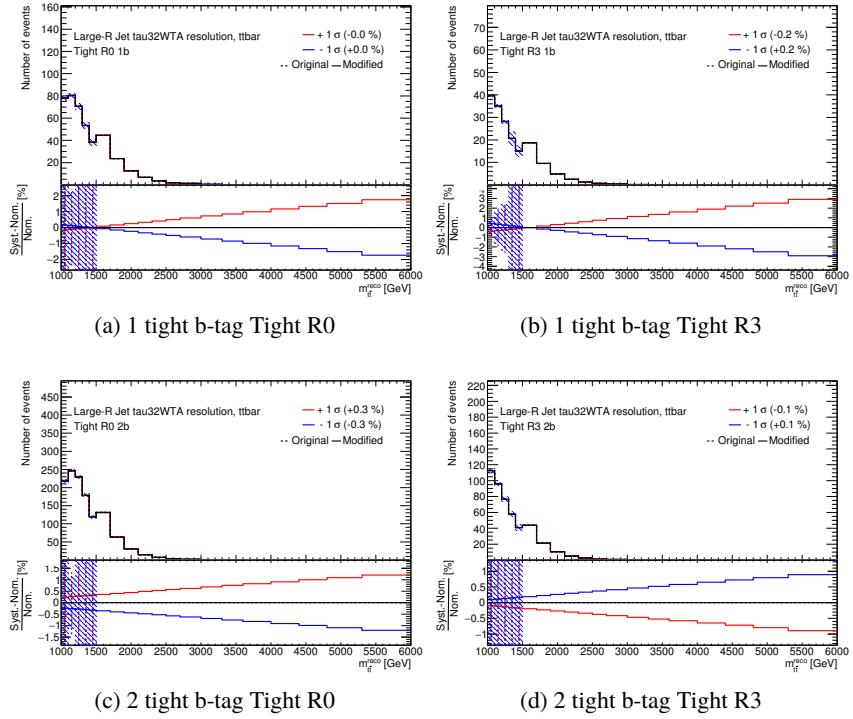

Figure 75: Systematic uncertainty associated with large- R jet τ_{32}^{wta} resolution distribution for Z' 3 TeV

8.4. Systematic uncertainty on $t\bar{t}$ modeling

The $t\bar{t}$ production cross section in pp collisions at $\sqrt{s} = 13$ TeV is $\sigma_{t\bar{t}} = 832^{+46}_{-52}$ pb for a top-quark mass of 172.5 GeV. It has been calculated at next-to-next-to leading order (NNLO) in QCD including resummation of next-to-next-to-leading logarithmic soft gluon terms with Top++2.0 [66–72].

The top-quark kinematics in $t\bar{t}$ events are corrected to account for electroweak higher-order effects [93]. This correction is applied to the generated events applyied as a function of the flavor and center-of-mass energy of the initial partons and on the decay angle of the top quarks in the center-of-mass frame of the initial partons. The value of the correction factor decreases with increasing $m_{t\bar{t}}$ from 0.98 at $m_{t\bar{t}} = 0.4$ TeV to 0.87 at $m_{t\bar{t}} = 3.5$ TeV. The impact of electroweak correction is estimated in Fig. 76.

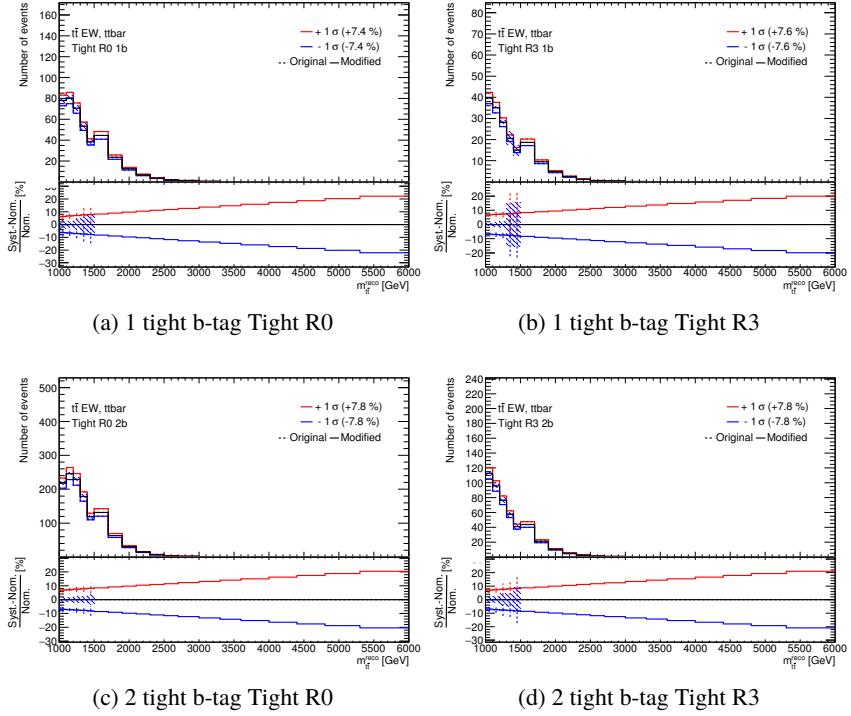

Figure 76: Impact of electroweak correction, i.e. $m_{t\bar{t}}$ before and after application of the EW weights.

The modeling uncertainties also come from what generator, parton shower model and other parameters are chosen. POWHEG + PYTHIA 6 is used as nominal sample for the SM $t\bar{t}$ background. The modeling uncertainties associated generator difference is estimated by comparing POWHEG + HERWIG ++ with aMC@NLO + HERWIG ++ (See Fig. 77). The modeling uncertainties associated parton shower model difference is estimated by comparing POWHEG + PYTHIA 6 with POWHEG + HERWIG ++ (See Fig. 78). Above two uncertainties are estimated with Eq. (42) and Eq. (43).

$$\Delta_{\text{generator}} (\%) = \frac{n_{\text{aMC@NLO + HERWIG ++}} - n_{\text{POWHEG + HERWIG ++}}}{n_{\text{POWHEG + HERWIG ++}}} \times 100 \quad (42)$$

$$\Delta_{\text{parton shower}} (\%) = \frac{n_{\text{POWHEG + HERWIG ++}} - n_{\text{POWHEG + PYTHIA 6}}}{n_{\text{POWHEG + PYTHIA 6}}} \times 100 \quad (43)$$

The modeling uncertainties associated ISR/FSR effect is estimated by comparing higher ISR/FSR conditions with lower ISR/FSR conditions in POWHEG + PYTHIA (See Fig. 79). This uncertainty is estimated with Eq. (44).

$$\Delta_{\text{ISRFSR}} (\%) = \frac{n_{\text{POWHEG + PYTHIA 6 high}} - n_{\text{POWHEG + PYTHIA 6 low}}}{2 \times n_{\text{POWHEG + PYTHIA 6 low}}} \times 100 \quad (44)$$

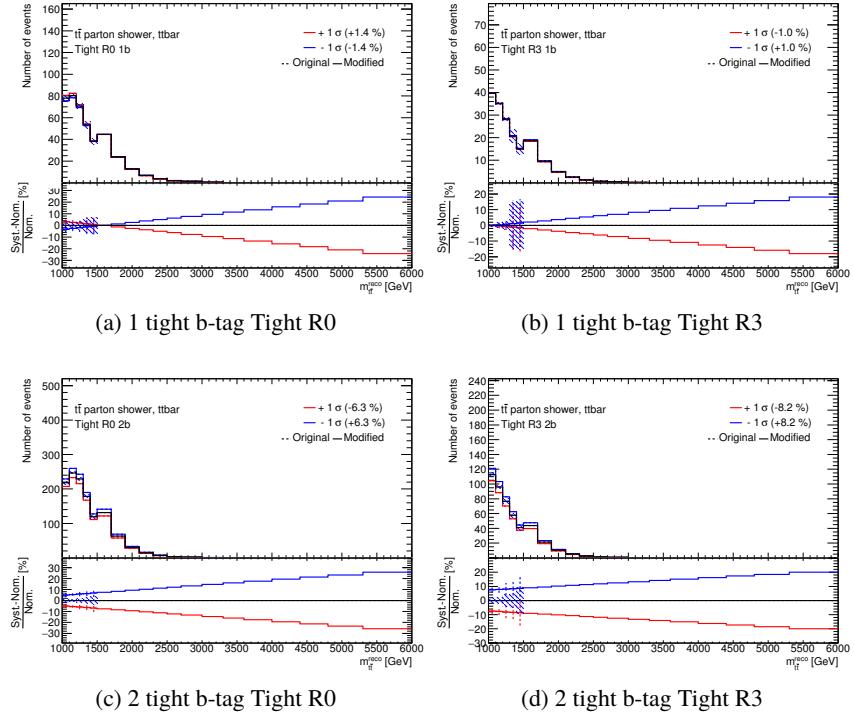

Figure 78: Systematics of different $t\bar{t}$ Monte Carlo parton showers models.

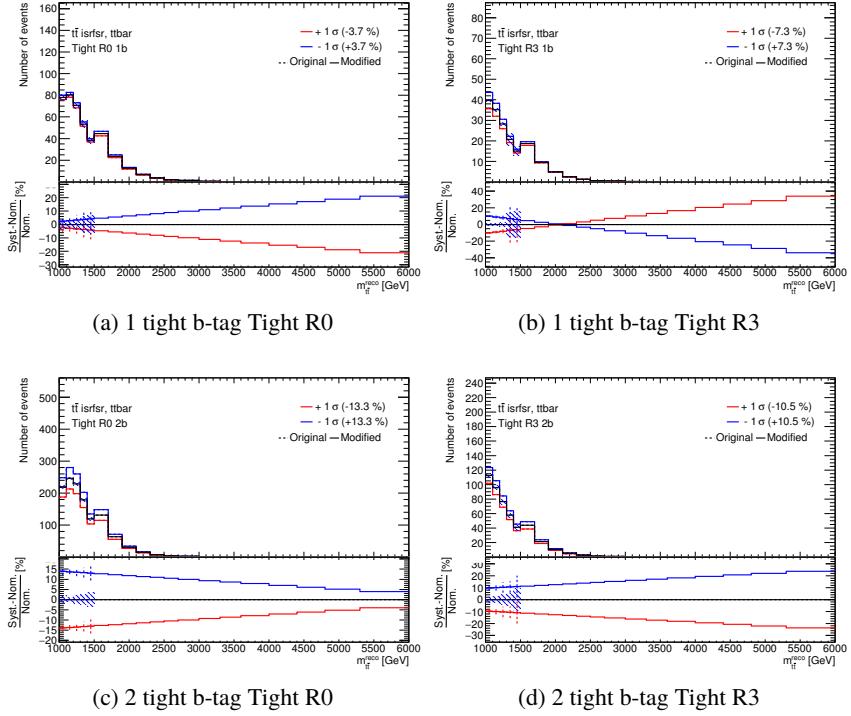

Figure 79: Systematics of different $t\bar{t}$ Monte Carlo ISR/FSR models

8.5. Systematic uncertainty on PDF

30 eigensets of the PDF4LHC_nlo_30 are used and the relative effect is taken as a systematic uncertainty in the Powheg +Pythia 6 sample for the SM $t\bar{t}$ background. Parts of the nominal $m_{t\bar{t}}$ distribution and systematic varied distribution for PDF uncertainty are shown in Fig. 80 for PDF CT10 v.s. PDF4LHC15, Fig. 81 for PDF eigenvalue 1. Bottom distributions are the differences between nominal and systematic varied distribution in those plots. This PDF CT10 v.s. PDF4LHC15 uncertainty does not depend on b-tag condition, therefore 1b and 2b distributions are merged to estimate this uncertainty in order to obtain statistics.

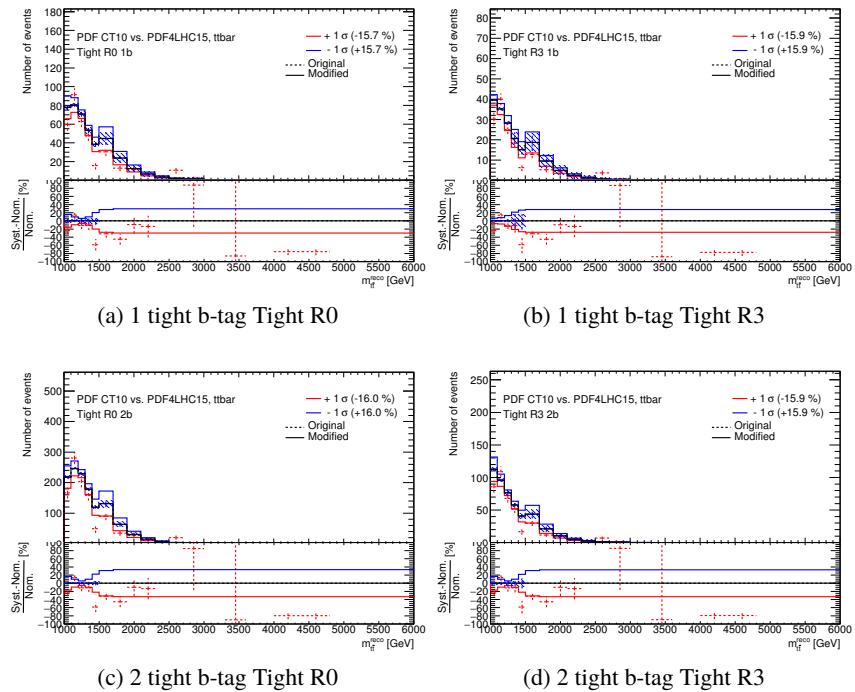

Figure 80: Systematics of PDF for the SM $t\bar{t}$ background

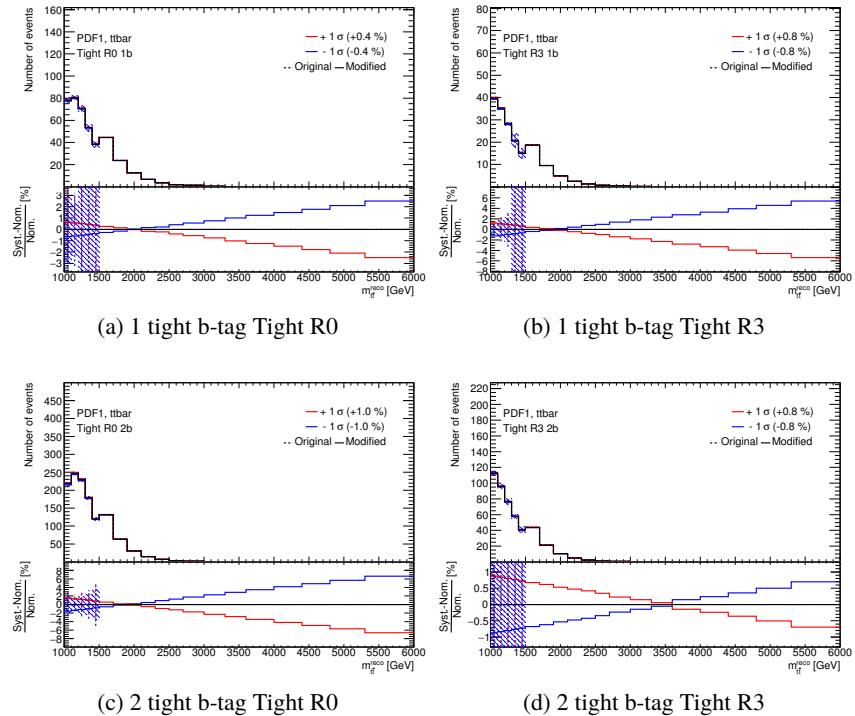

Figure 81: Systematics of PDF for the SM $t\bar{t}$ background

8.6. Systematic uncertainty on multi-jet backgrounds estimation

Two uncertainties are considered for the multi-jet background estimation, one is on the normalization, and the other is on the shape.

As mentioned in earlier (Sec. 7.2), the normalization factor n_{category} is estimated from a simple average of the four control regions (Eq. (40)). This normalization factor has slight difference in the four control regions. We take the maximum deviation $\Delta_{+,-}$ from the averaged value, and assign it as a systematic uncertainty. The deviation $\Delta_{+,-}$ is defined as in Eq. (45) and Eq. (46).

$$\Delta_+ = \frac{n_{\text{maximum}} - n_{\text{category}}}{n_{\text{category}}} \quad (45)$$

$$\Delta_- = \frac{n_{\text{category}} - n_{\text{minimum}}}{n_{\text{category}}} \quad (46)$$

The systematic uncertainty on this QCD multi-jet background estimation is obtained from a possible residual difference after the correction, and the uncertainty on the fitting. The residual shape difference in $m_{t\bar{t}}$ is fitted by a linear function and the difference of the slope from unity is assigned as a shape systematic uncertainty, as shown in Fig. 82.

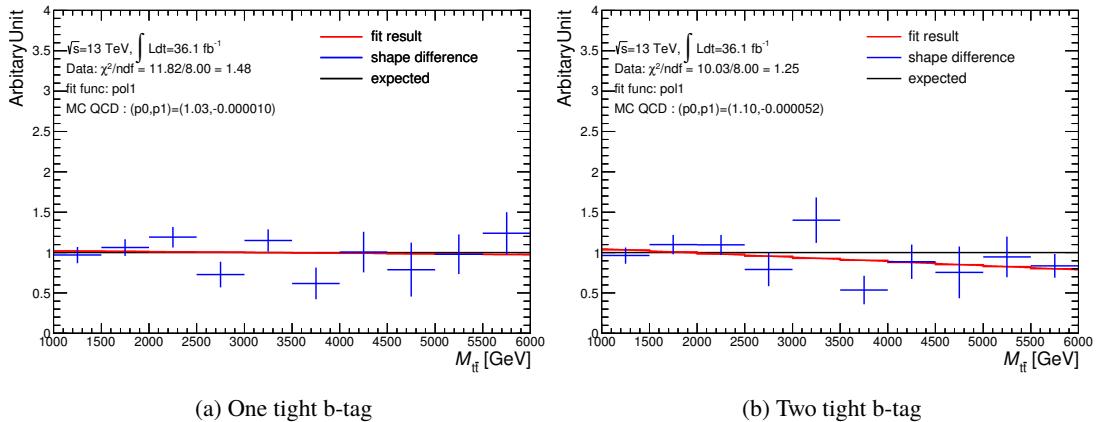

Figure 82: Extraction of possible residual difference after the shape correction. Left is for one tight b-tagged events, and right is for two tight b-tagged events.

Systematic uncertainty from the fitting uncertainty is estimated by varying the fit parameter, $p0$ and $p1$, by one sigma while other parameters are floated. Figure 83 shows the variations of this systematics effect, which is used to assign corresponding systematic uncertainty. Variation of the parameter $p2$ is not considered as a systematic uncertainty because the effect is found to be negligible.

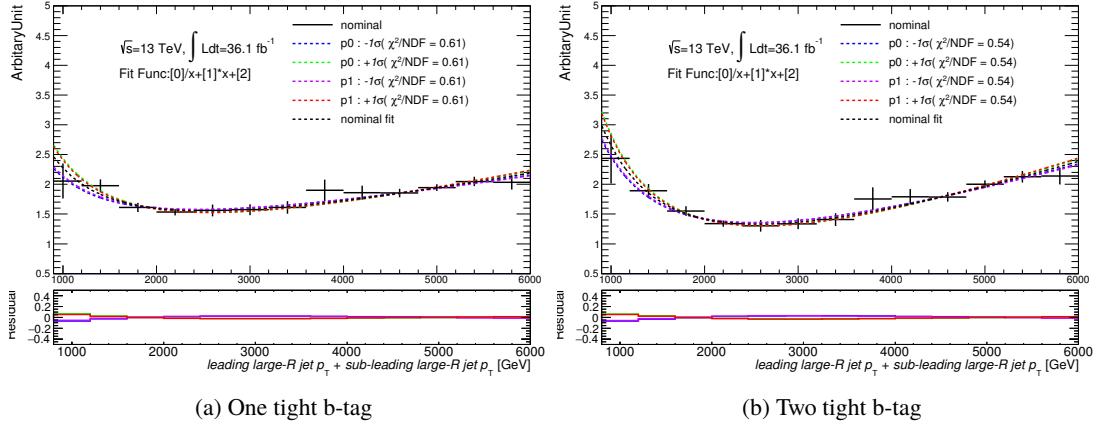

Figure 83: Statistical variations of the correction function.

The shapes of the multi-jet background template for the Loose, Medium, and Tight are consistent within statistical uncertainties. However, we took difference between the merged distribution and each distribution as a systematic uncertainty conservatively. To do this we use events in the control regions (CR1,2,3,4) in order to estimate this systematics reasonably with enough statistics, because the statistics in the signal regions is very limited. Estimated systematic uncertainties are showed in Fig. 84. One can see larger systematic uncertainty at lower mass region, this is because the τ_{32}^{wta} -likelihood ratio has a dependence on jet p_T particularly at low p_T region. One tight b-tagged and two tight b-tagged multijet background distributions are estimated from a common template distribution, therefore the systematic uncertainty is treated as fully-correlated uncertainty for one tight b-tag and two tight b-tag.

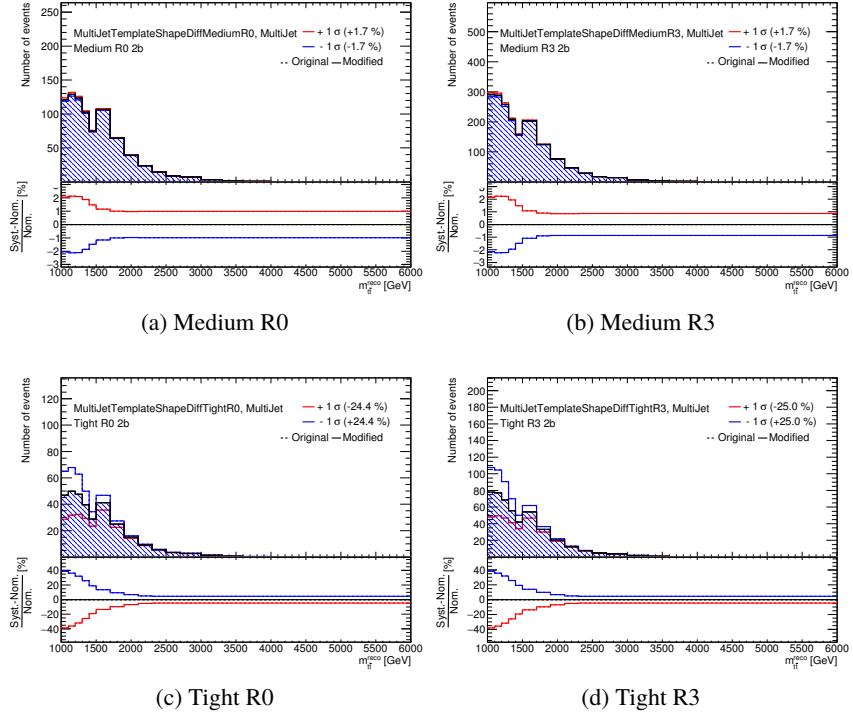

Figure 84: Multijet template shape difference between the merged category and each category.

In addition to them, the multijet background estimation at lower mass region ($m_{t\bar{t}} < 1.5$ TeV) is using histogram instead of the exponential extrapolation. Therefore, the uncertainty at low mass region is simply bin-by-bin statistical uncertainties from the original histogram. As the multijet template for the one tight b-tag and two tight b-tag regions is common (from zero tight b-tag), therefore we treat the bin-by-bin uncertainties 100% correlated between one tight b-tag and two tight b-tag regions.

8.7. Systematic uncertainty on extrapolation

Systematic uncertainty on this extrapolation method (See Sec. 7.3) includes statistical uncertainty of the fit, and stability of the fit range choice. Stability of the fit range choice is evaluated by taking the maximum deviation from the nominal slope parameter when changing the lower edge of the fit range, until the statistical fluctuation becomes large. The nominal fit range is from 1.2 TeV to 4 TeV, and another fit range to estimate systematic uncertainty of this is from 1.7 TeV to 4 TeV. The estimated systematic uncertainties are shown in Fig. 85 for the multijet background, and in Fig. 86 for the SM $t\bar{t}$ background.

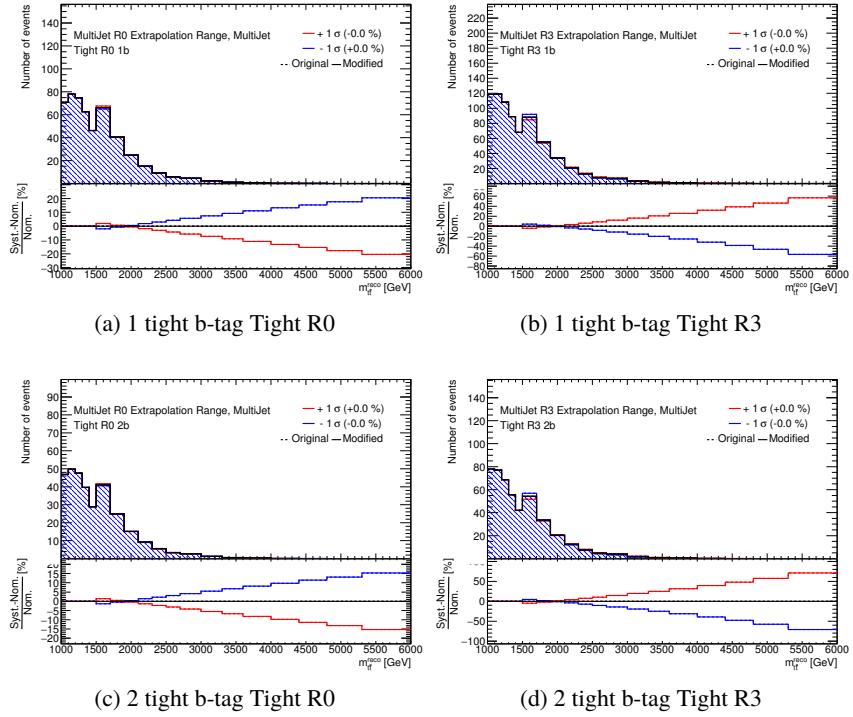

Figure 85: Systematic distributions of $m_{t\bar{t}}$ for fit range variation of extrapolation. Data Driven multijet.

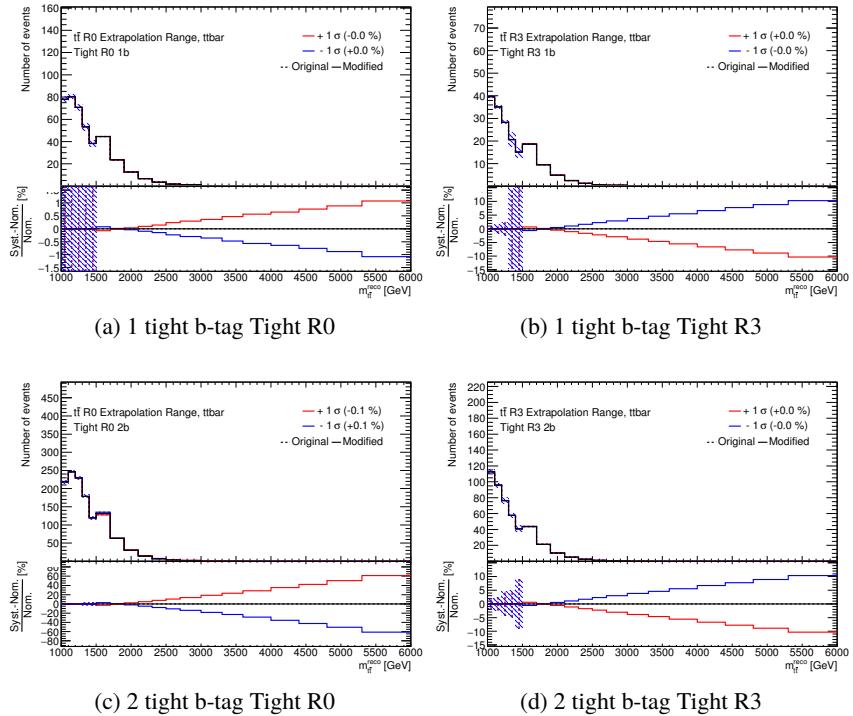

Figure 86: Systematic distributions of $m_{t\bar{t}}$ for fit range variation of extrapolation. Data Driven multijet.

The statistical uncertainty of the fit is evaluated by varying the slope parameter by ± 1 sigma, as can be seen in Fig. 87, 88 for QCD multijet background and 89, 90 for the Standard Model $t\bar{t}$ background, respectively. An alternative function, dijet mass function ($p_0 \times (1 - \frac{x}{\sqrt{s}})^{p_1} \times (\frac{x}{\sqrt{s}})^{p_2}$), is also tried, and it is observed that the extrapolation shapes are consistent with the nominal function (exponential) within the statistical uncertainty.

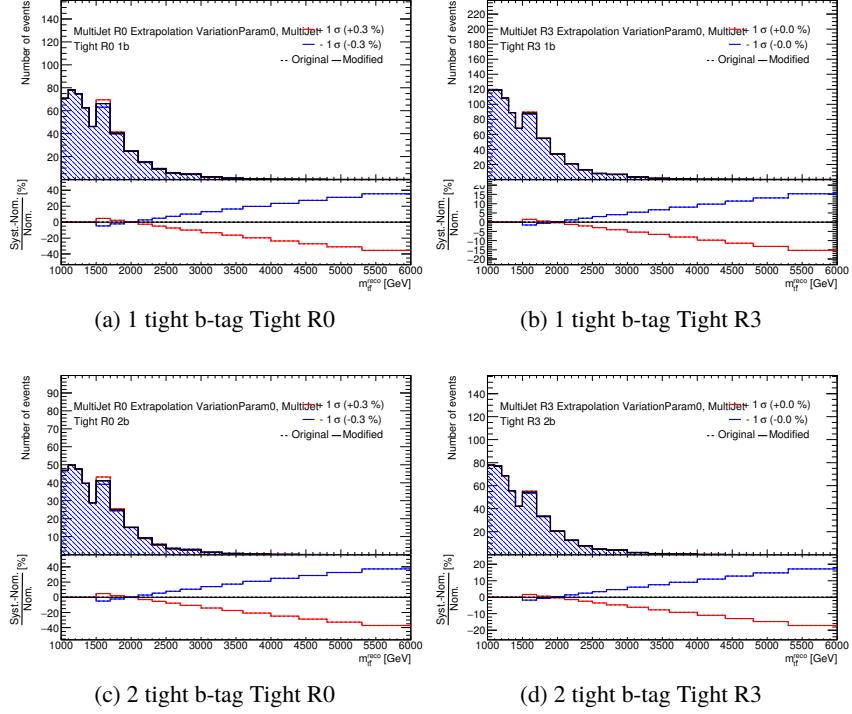

Figure 87: Systematic distributions of $m_{t\bar{t}}$ for p_0 parameter. Data Driven multijet.

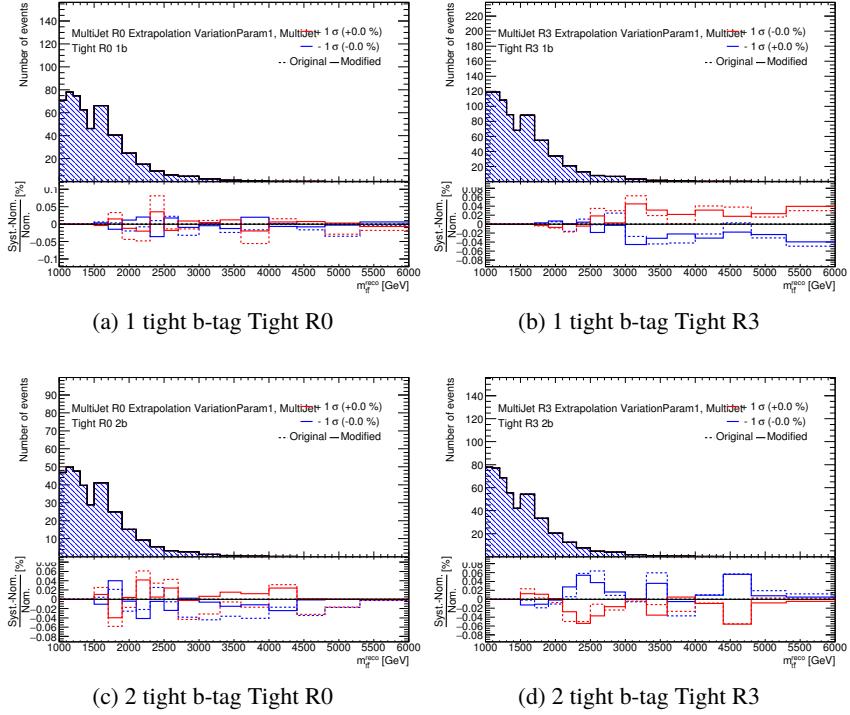

Figure 88: Systematic distributions of $m_{t\bar{t}}$ for p1 parameter. Data Driven multijet.

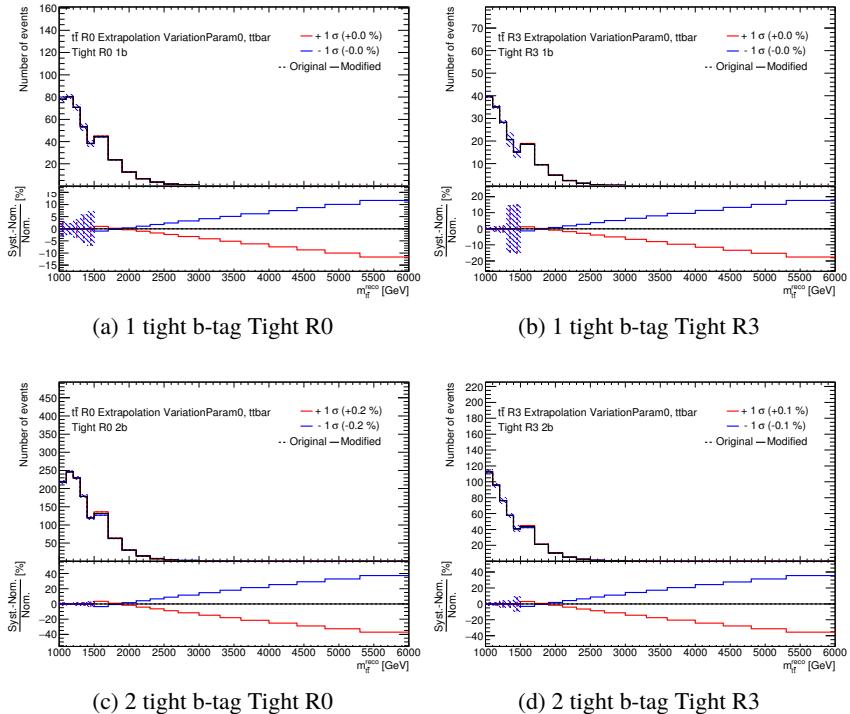

Figure 89: Systematic distributions of $m_{t\bar{t}}$ for p0 parameter. MC $t\bar{t}$.

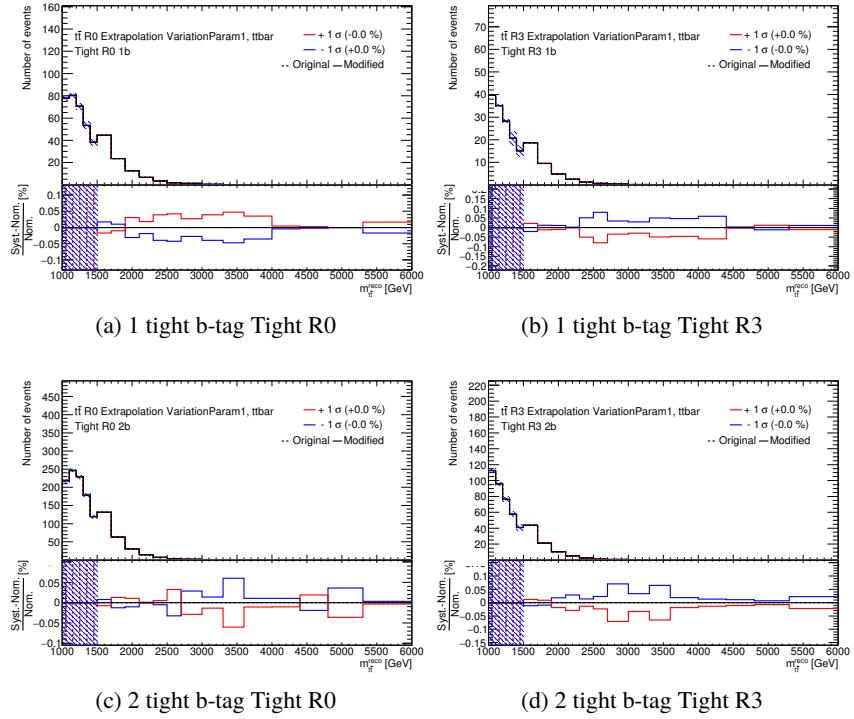

Figure 90: Systematic distributions of $m_{t\bar{t}}$ for p1 parameter. MC $t\bar{t}$.

In addition, the extrapolation is started from 1.5 TeV, and statistical uncertainty above 1.5 TeV is replaced to the systematic uncertainty associated with fit error variation. Therefore $m_{t\bar{t}}$ distribution above 1.5 TeV don't have statistical uncertainty. Statistical uncertainties below 1.5 TeV are remained, but the statistical uncertainty for multijet have to be fully-correlated between one tight b-tag and two tight b-tag, because one tight b-tagged and two tight b-tagged multijet distributions are estimated by a common no tight b-tagged distribution. Hence, the statistical uncertainties are also replaced to systematic uncertainty in order to treat them as bin-by-bin and fully-correlated uncertainty between one tight b-tag and two tight b-tag. Figure 91 and 92

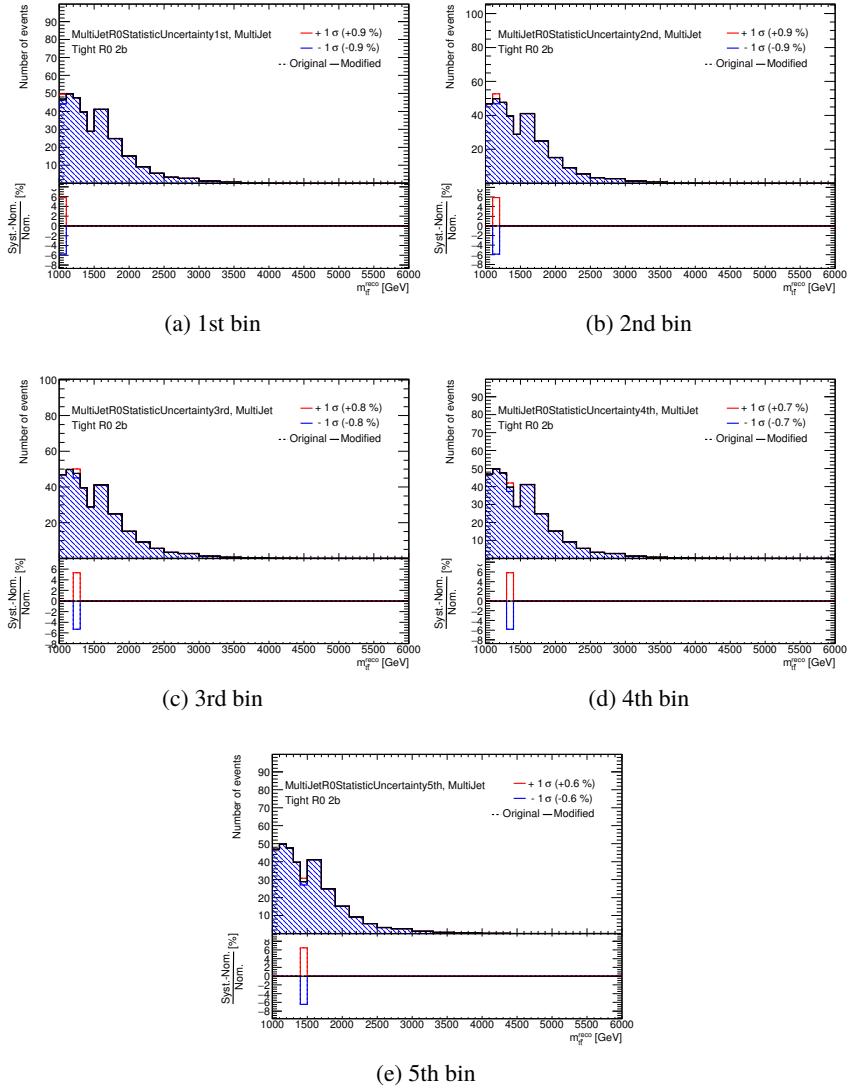

Figure 91: Systematic distributions of $m_{t\bar{t}}$ for statistical uncertainty in R0 Tight 2 tight b-tagged region.

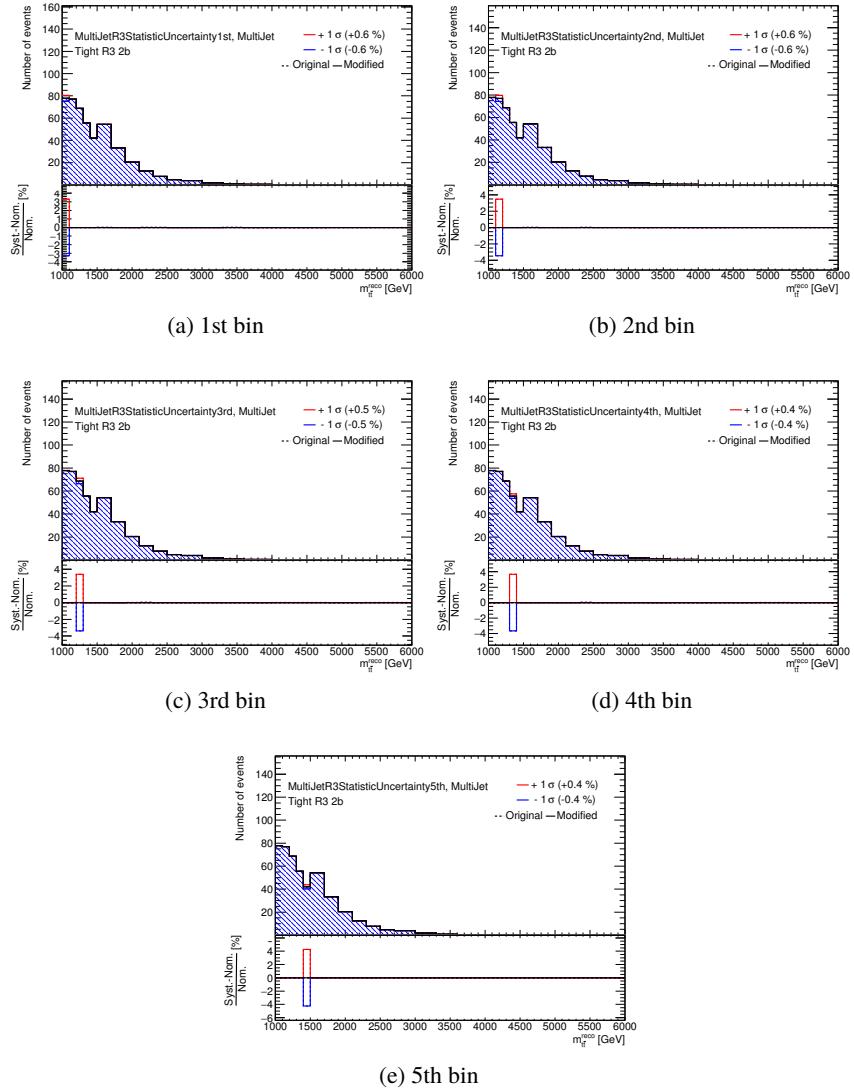

Figure 92: Systematic distributions of $m_{t\bar{t}}$ for statistical uncertainty in R3 Tight 2 tight b-tagged region.

8.8. Summary of systematic uncertainty

Table 15 is showed relative effect of each systematic uncertainty on the yields for 2 tight b-tagged Tight R0, and the summary for other regions can be seen in Appendix. B.

8.9. Validation

In order to validate the estimated background modelings, we checked events in the validation regions. We define the validation region as the events in the Loose regions.

Table 15: Relative effect of each systematic on the yields for two tight b-tagged Tight R0.

Purity of the Standard Model $t\bar{t}$ background events in the validation regions is summarized in Table. 16. The purity in each validation region is a few%, contribution of multijet background is dominant in validation region. Therefore, signal contamination is negligible.

Table 16: Purity of the Standard Model $t\bar{t}$ events in validation regions.

validation region	purity in no tight b-tag	purity in 1 tight b-tag	purity in 2 tight b-tag
VR0-Loose	$(1.7 \pm 0.25)\%$	$(7.28 \pm 0.23)\%$	$(25.6 \pm 0.86)\%$
VR1-Loose	$(0.63 \pm 0.13)\%$	$(2.74 \pm 0.20)\%$	$(9.50 \pm 0.45)\%$
VR2-Loose	$(0.64 \pm 0.17)\%$	$(2.8 \pm 0.19)\%$	$(8.36 \pm 0.39)\%$
VR3-Loose	$(0.83 \pm 0.08)\%$	$(3.72 \pm 0.12)\%$	$(13.13 \pm 0.29)\%$
VR4-Loose	$(0.48 \pm 0.06)\%$	$(2.21 \pm 0.10)\%$	$(6.88 \pm 0.20)\%$

The shape of the multijet background in the Loose region is obtained from the merged regions (Loose+Medium+Tight).

The shape correction for the multijet background modeling for merged region has already validated in Section 7.2.

The estimated background distributions are compared with the data in the validation region as can be seen in Fig.s 93 and 94. The background distributions using the extrapolation method are also shown there. As can be seen, the expected distributions agree well with the data.

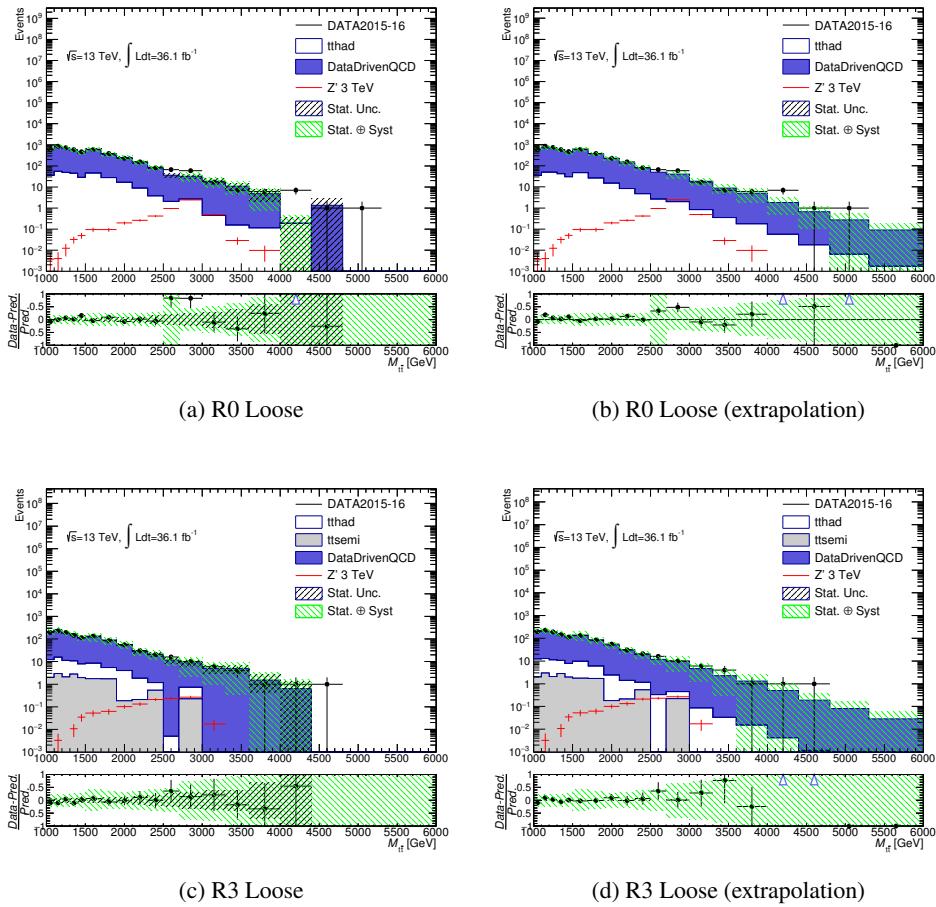

Figure 93: Distributions of $m_{t\bar{t}}$ in one tight b-tagged validation region .

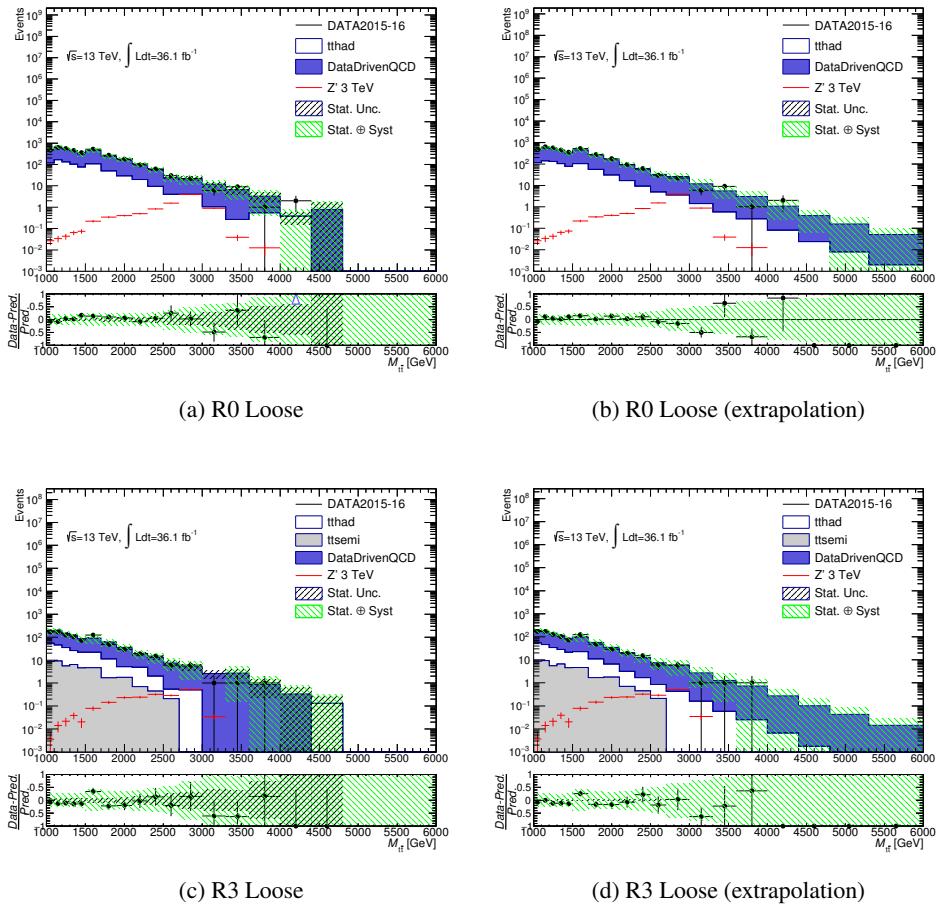

Figure 94: Distributions of $m_{t\bar{t}}$ in two tight b-tagged validation region.

8.9.1. Fit results of the Loose R0+R3

In order to check if estimated background and systematic uncertainties are reasonable or not, the $m_{t\bar{t}}$ distributions in the validation regions are fitted, the cross section limits are produced, in the same way as we do for the signal region. Figure 95, 96 show the nuisance parameters and the correlation matrix of each nuisance parameters, the expected size of constraint from the fitting in the Loose R0+R3. Multijet statistic uncertainties for each bin are pulled, but this kind of uncertainties are expected to be widely moved. The other nuisance parameters are stable. For correlation matrix, some multijet normalization factor uncertainties are correlated to multijet shape correction uncertainty. The multijet shape correction uncertainty has a normalization component, therefore it can be understood. In addition, other correlated uncertainties are same kinds of systematic uncertainty between each other, therefore it is reasonable that there is a correlation between same kinds of uncertainty.

Pre-fit and Post-fit $m_{t\bar{t}}$ distributions are showed in Fig. 97 and 98.

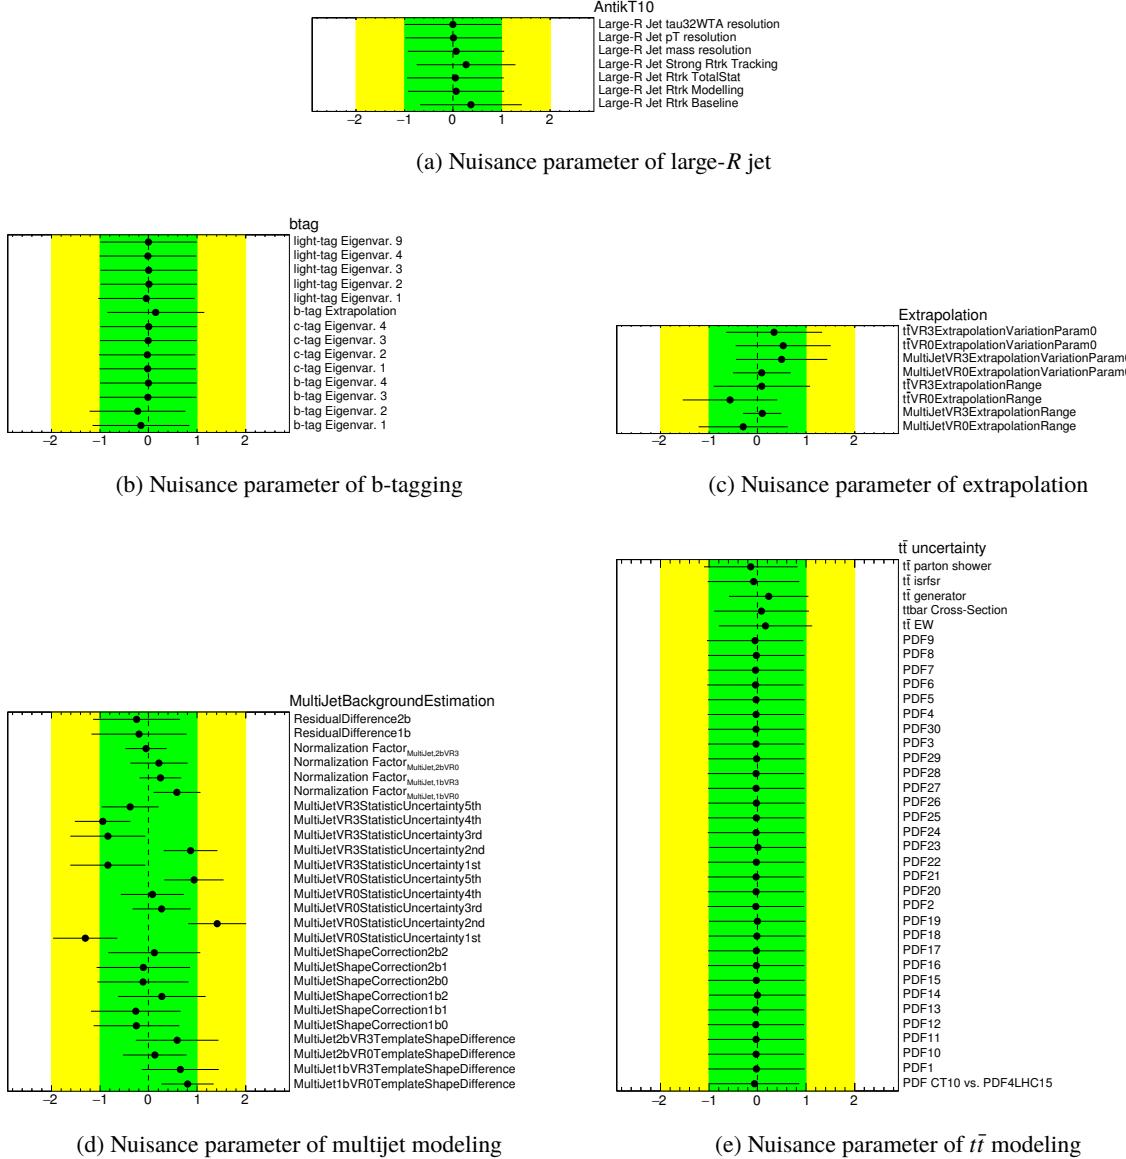

Figure 95: Pull plots of each nuisance parameter. The data points denote an impact of each nuisance parameter for the fit. The error bars denote the expected size of constraint from the fitting to each nuisance parameter.

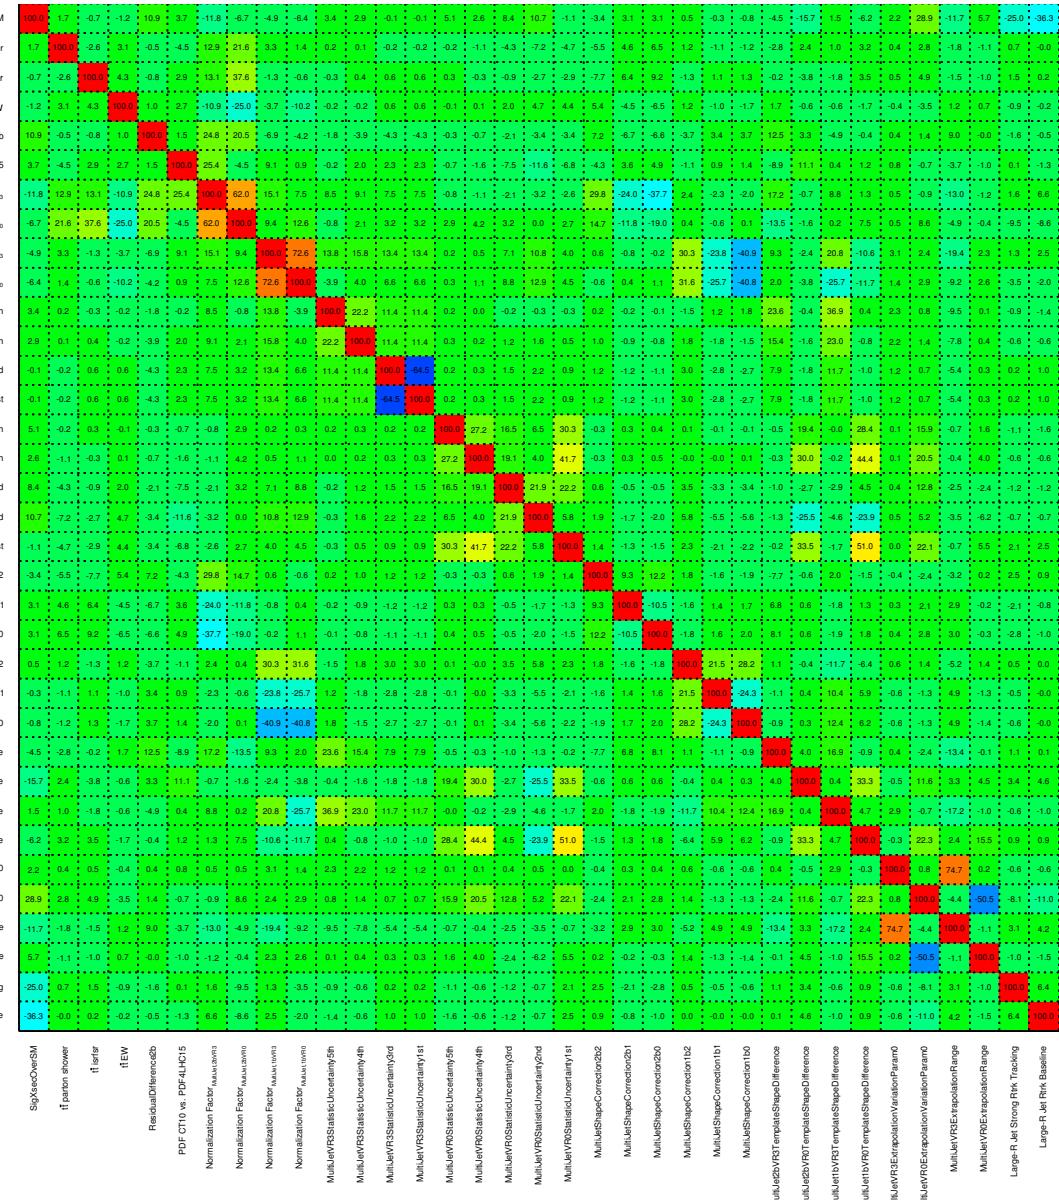

Figure 96: Correlation matrix of the nuisance parameters. Only those with correlation above 20% are shown

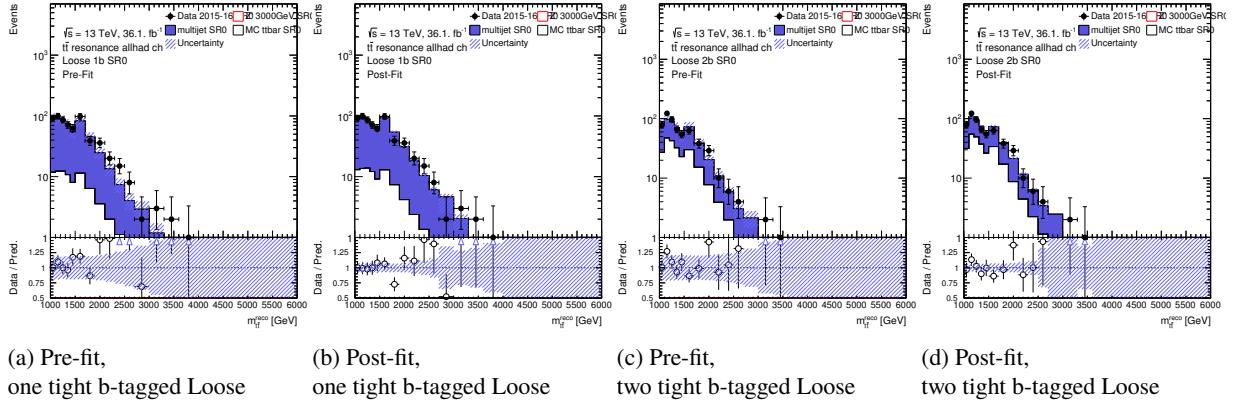

Figure 97: Pre-fit and Post-fit $m_{t\bar{t}}$ distributions for the validation region, R0 Loose and one or two tight b-tagged.

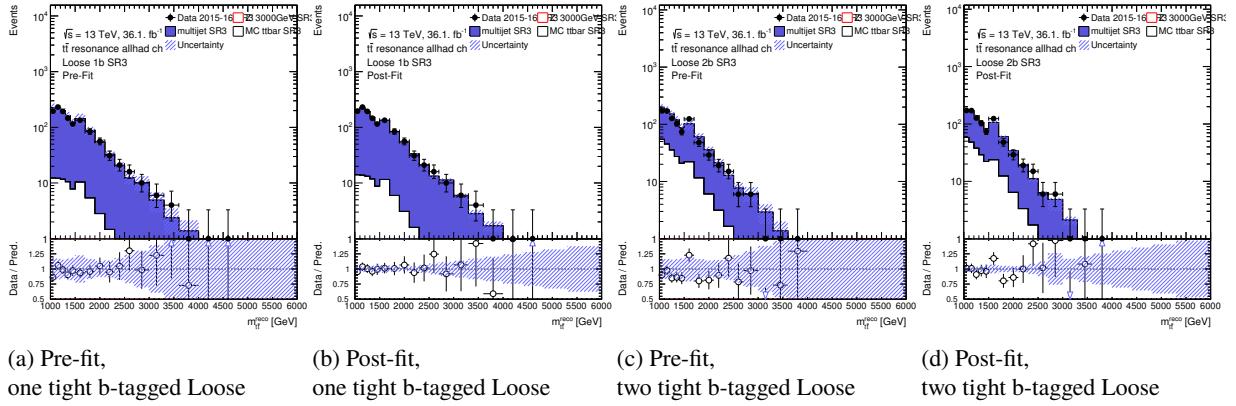

Figure 98: Pre-fit and Post-fit $m_{t\bar{t}}$ distributions for the validation region, R3 Loose and one or two tight b-tagged.

Fit result of Z' without systematic uncertainties is showed in Fig. 99.

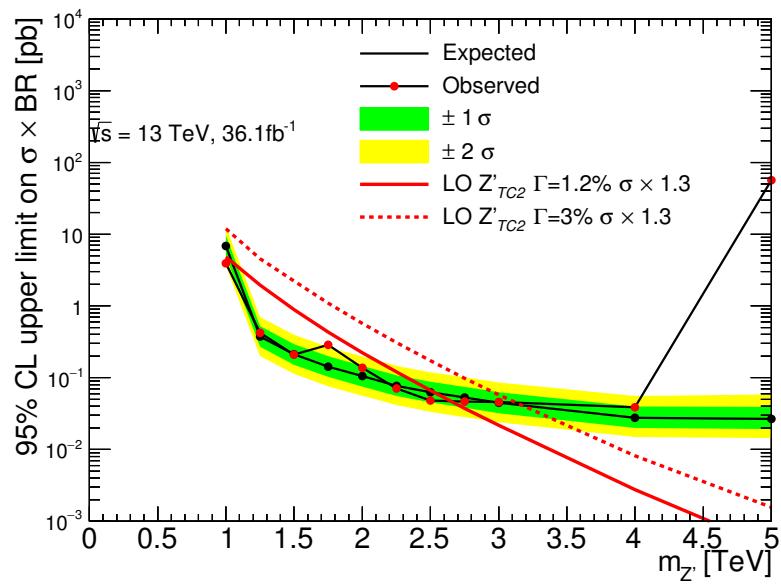

Figure 99: Extracted and observed upper limits on Z' with no systematic uncertainty

Result from a fit with all the systematic uncertainties is shown in Fig. 100. The observed limits well agree with the expected limits.

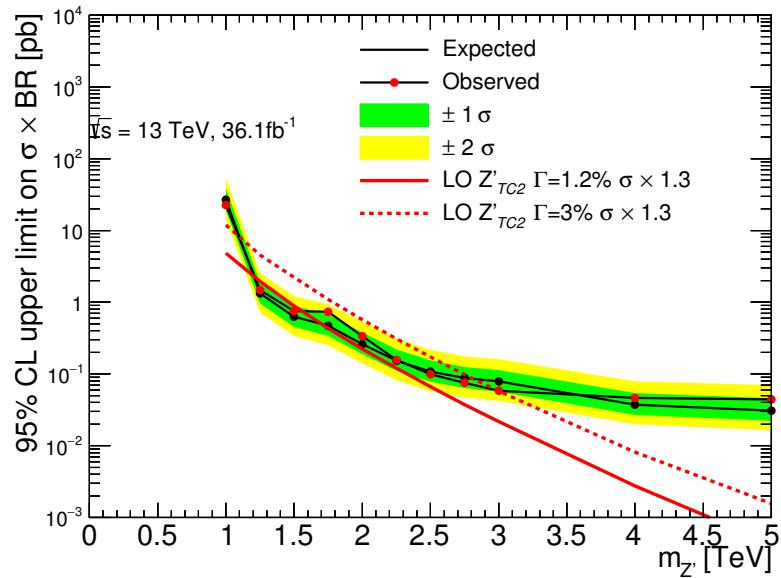

Figure 100: Extracted and observed upper limits on Z' with all systematic uncertainty

9. Results

The $m_{t\bar{t}}$ distributions in one or two tight b-tagged R0 and R3 for Medium and Tight category are used as the final discriminants.

The amount of the Standard Model $t\bar{t}$ background events in the signal regions is summarized in Table. 17. Figure 101, 102, 103 and 104 show the distributions of $m_{t\bar{t}}$ in the R0 and R3 (data points are not shown). Background estimations using the extrapolation are shown separately. Figure 105 and 105 show the number of expected events in each region, and the number of observed events in data.

Table 17: Amount of the Standard Model $t\bar{t}$ events in signal regions.

signal	amount in no tight b-tag	amount in 1 tight b-tag	amount in 2 tight b-tag
R0-Medium	(4.90 ± 0.60)%	(17.92 ± 0.77)%	(51.08 ± 1.61)%
R0-Tight	(14.96 ± 1.84)%	(44.38 ± 1.97)%	(76.08 ± 2.24)%
R3-Medium	(1.80 ± 0.27)%	(8.09 ± 0.36)%	(27.51 ± 0.86)%
R3-Tight	(5.31 ± 0.89)%	(17.86 ± 1.03)%	(46.07 ± 1.91)%

9.1. Profile likelihood fit

Upper limits are set on the cross-section times signal branching ratio for each new physics model with a profile likelihood fit [94]. A value x is observed for each event, and a histogram $\mathbf{n} = (n_1, \dots, n_N)$ is constructed by those events. In this analysis, the x is equal to each observed $m_{t\bar{t}}$ value. The expectation value of n_i can be written as

$$E[n_i] = \mu s_i + b_i, \quad (47)$$

where μ denotes the strength of the signal process, s_i and b_i are the mean number of the entries in the i th bin from signal and background. They satisfy

$$s_i = s_{tot} \int_{\text{bin } i} f_s(x; \theta_s) dx, \quad (48)$$

$$b_i = b_{tot} \int_{\text{bin } i} f_b(x; \theta_b) dx, \quad (49)$$

where s_{tot} and b_{tot} denote the total mean numbers of signal and background, the functions $f_s(x; \theta_s)$ and $f_b(x; \theta_b)$ are probability density functions of value of the x for signal and background, and the parameters θ_s and θ_b denote parameters which characterize the shape of probability density function. The value s_{tot} depends on and is determined from the expected signal model. Nuisance parameters of this fit can be written as $\theta = (\theta_s, \theta_b, b_{tot})$. The likelihood function can be written as

$$L(\mu, \theta) = \prod_{j=0}^N \frac{(\mu s_j + b_j)^{n_j}}{n_j!} e^{-(\mu s_j + b_j)}. \quad (50)$$

In order to test a hypothesis value of μ , the profile likelihood ratio is considered as

$$\lambda(\mu) = \frac{L(\mu, \hat{\theta})}{L(\hat{\mu}, \hat{\theta})}, \quad (51)$$

where $\hat{\theta}$ denotes the θ maximize L for μ , and the denominator of Eq. (51) is the maximized likelihood function for $\hat{\mu}$ and $\hat{\theta}$.

9.2. Fitting result for signal region

Figure 107 shows impact of each nuisance parameter for the fit. The error bars show the expected size of constraint from the fitting to each nuisance parameter. Nuisance parameter of extrapolation uncertainty and multijet template shape uncertainty are constrained, because those uncertainties are larger than the other uncertainties. Therefore, those uncertainties are strongly constrained by fitting.

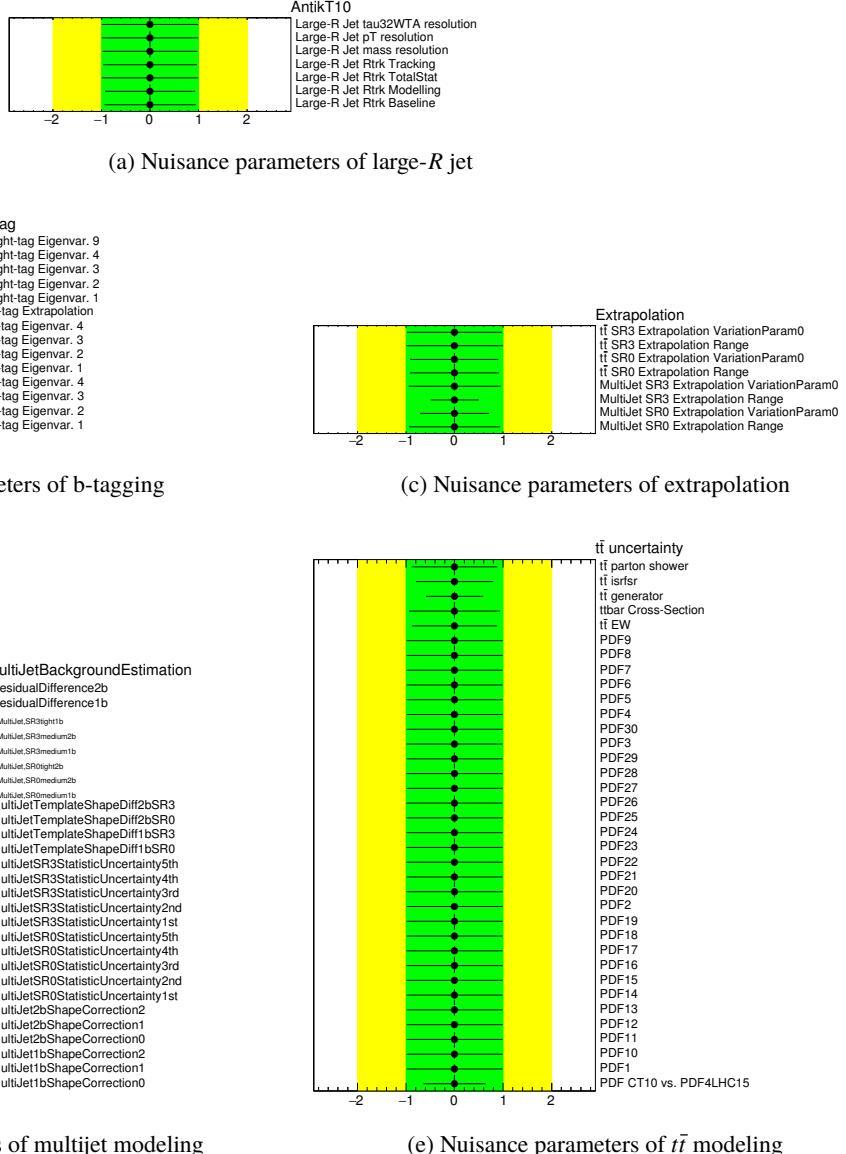

Figure 107: Pull plots of each nuisance parameter. The data points denote an impact of each nuisance parameter for the fit. The error bars denote the expected size of constraint from the fitting to each nuisance parameter.

Figure 108 shows the correlation matrix of each nuisance parameter. There are a bit strongly correlated components, but the nuisance parameters in each components are similar type of systematic uncertainty. Therefore, it can be understood that the correlation became a bit strong.

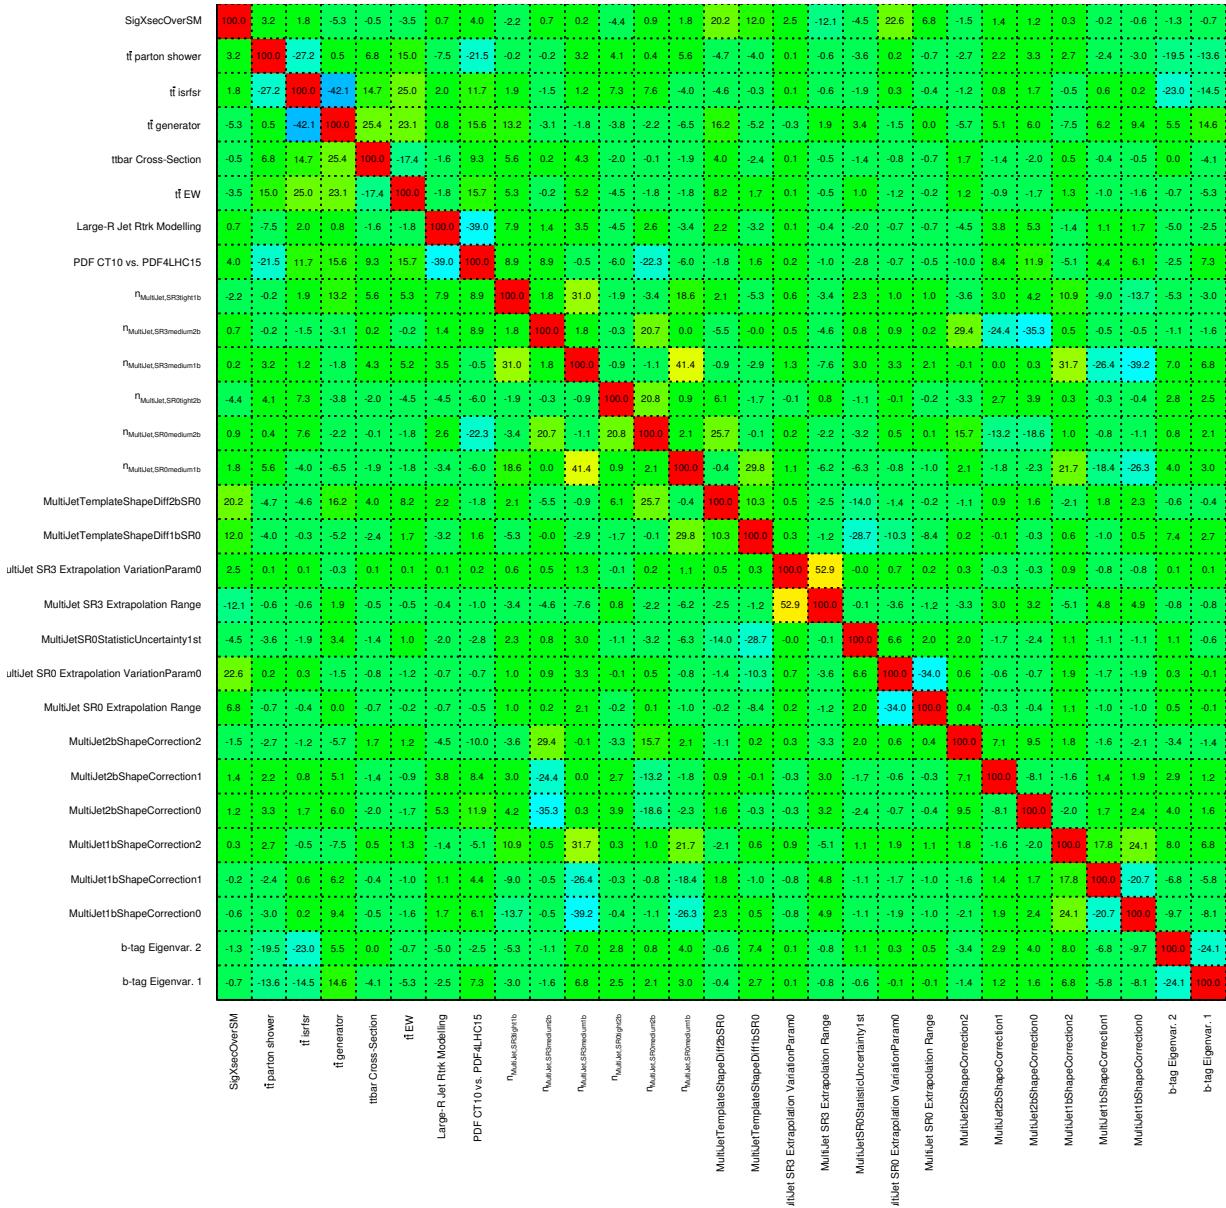

Figure 108: Correlation matrix of the nuisance parameters. Only those with correlation above 20% are shown

Figure 109 show the impact on signal strength for each nuisance parameters for Z' 1, 2 and 3 TeV MC samples. At 1 and 2 TeV, $t\bar{t}$ modeling uncertainties are dominant. Extrapolation uncertainties are dominant at 3 TeV.

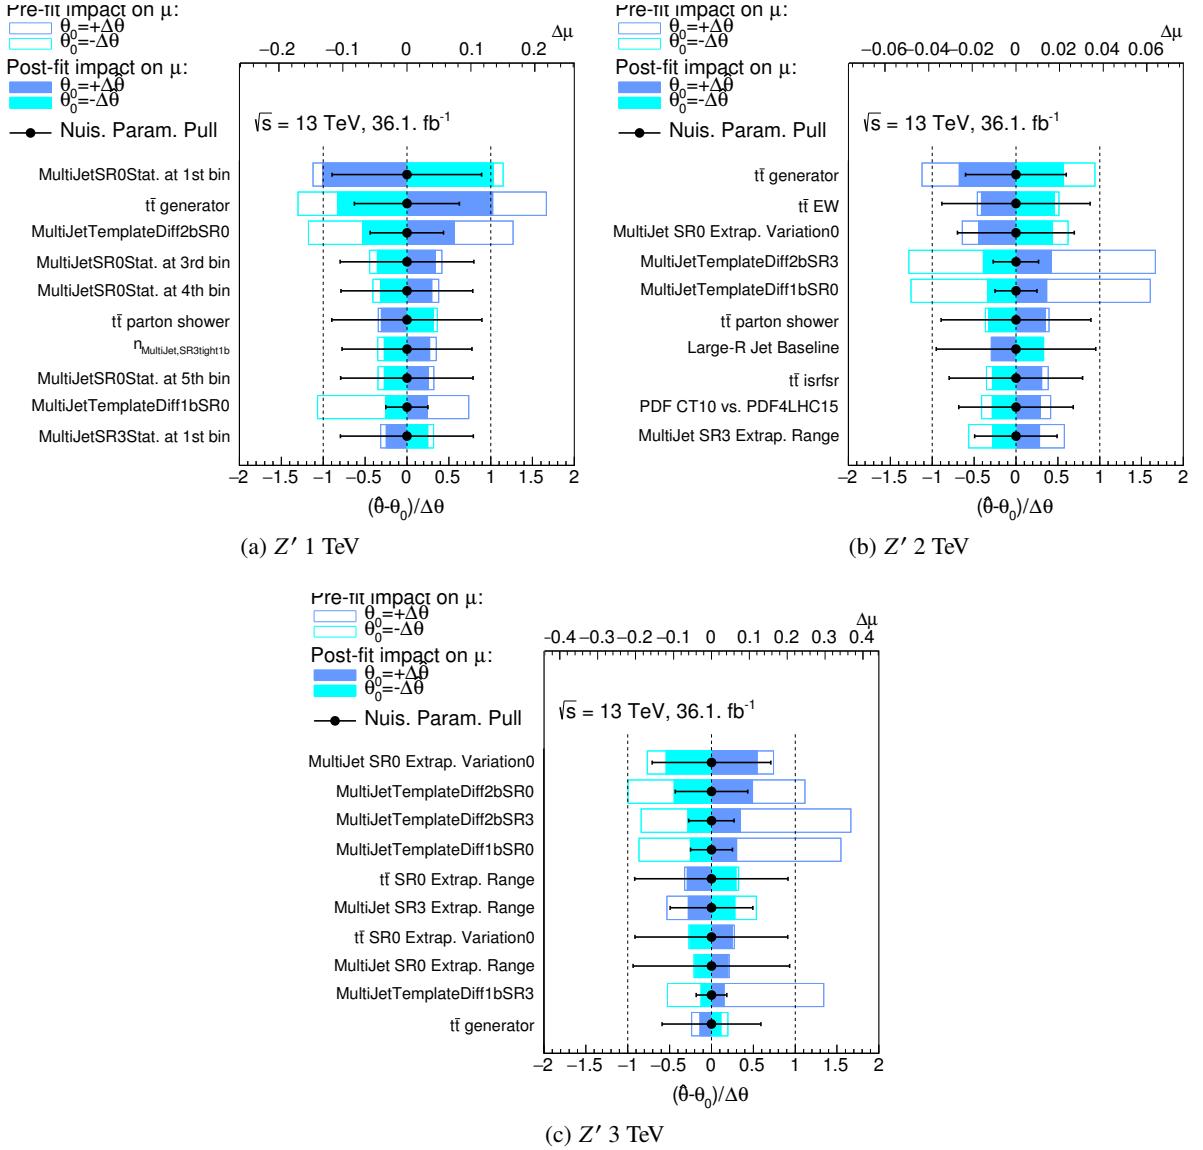

Figure 109: The impact on signal strength for each nuisance parameters. Top 10 nuisance parameters are shown.

The $m_{t\bar{t}}$ distributions before and after fitting (Called “pre-fit” and “post-fit”, respectively) are shown in Figs. 110 and 111.

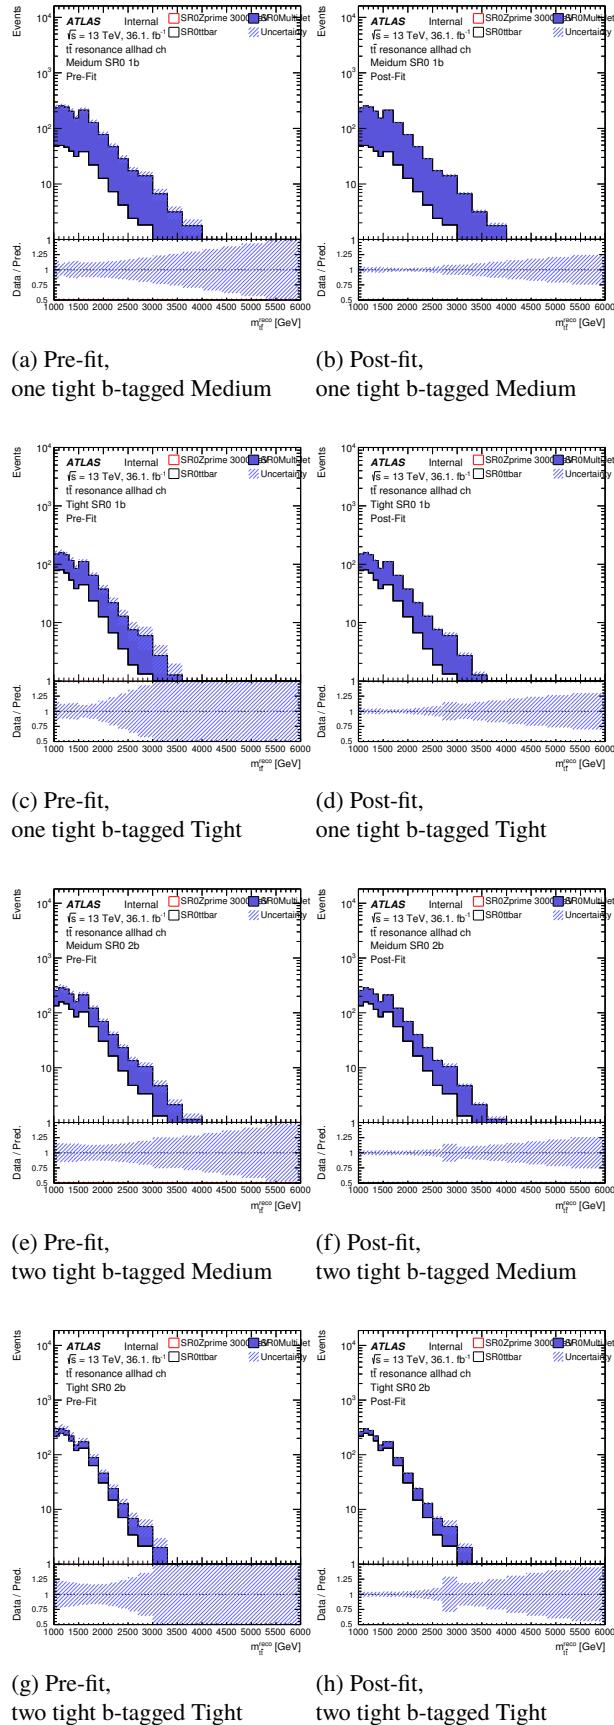

Figure 110: Pre-fit and Post-fit $m_{t\bar{t}}$ distributions for the signal region, R0 Medium or Tight and one or two tight b-tagged.

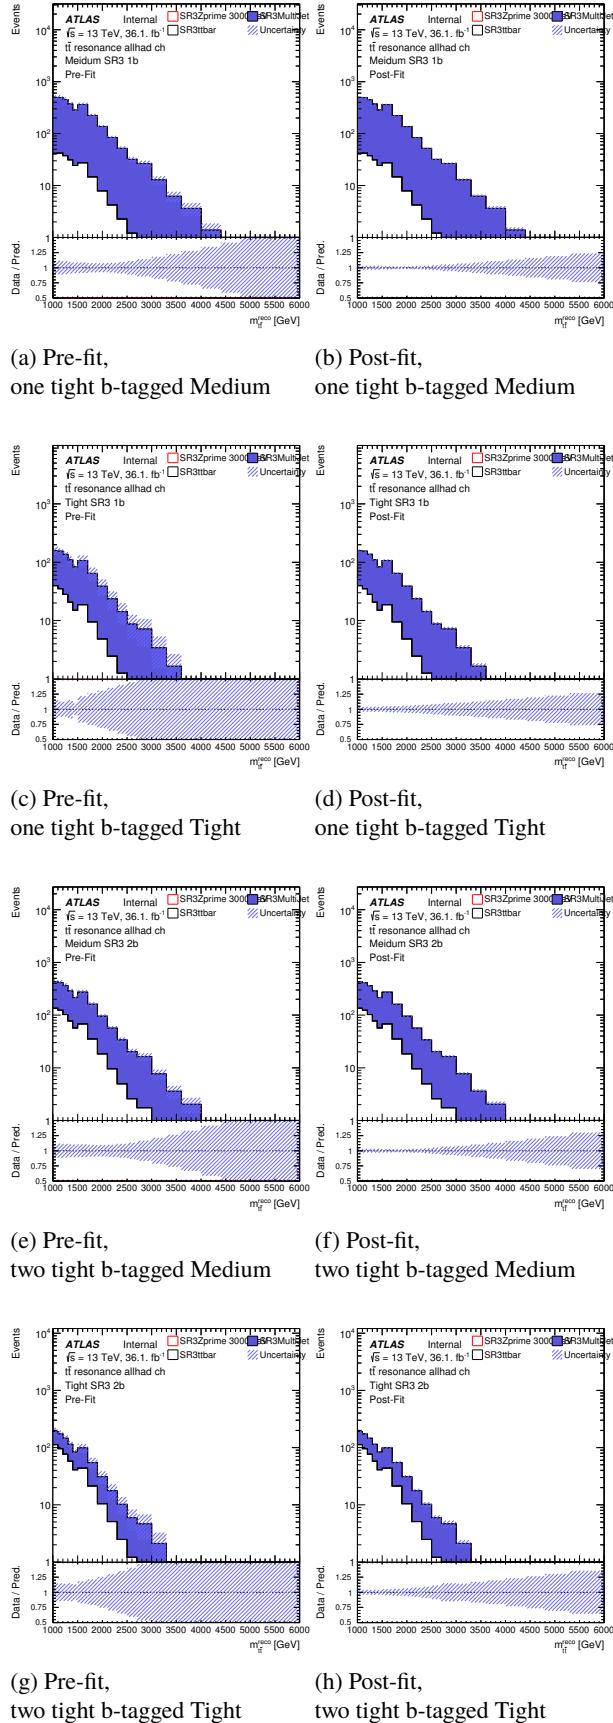

Figure 111: Pre-fit and Post-fit $m_{t\bar{t}}$ distributions for the signal region, R3 Medium or Tight and one or two tight b-tagged.

The fit result for Z' signal without systematic uncertainties is shown in Fig. 112.

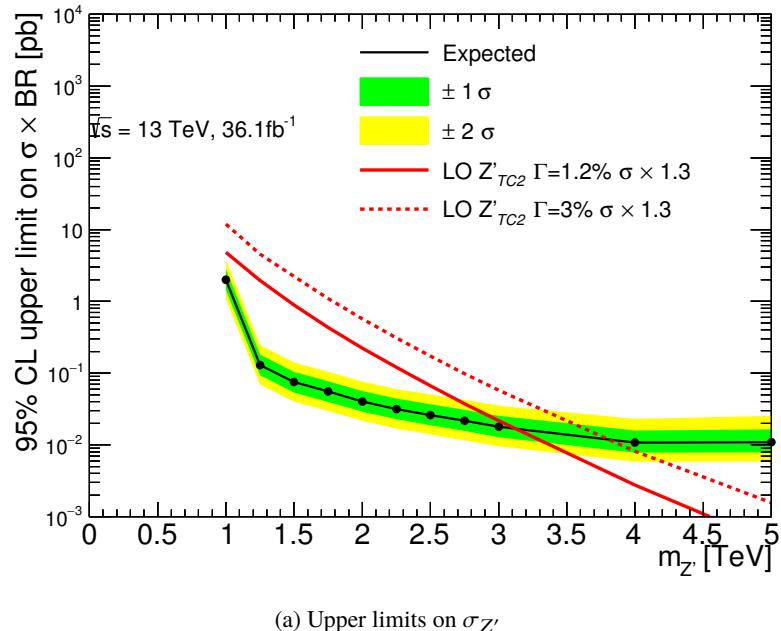

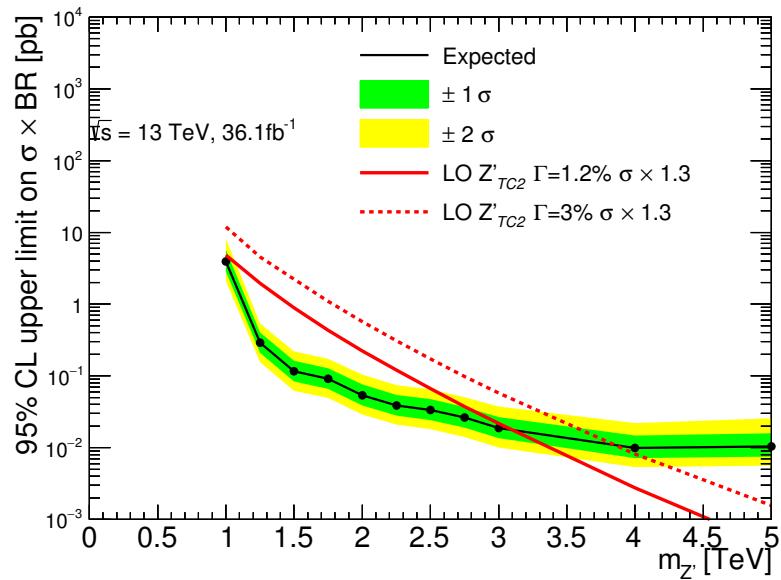

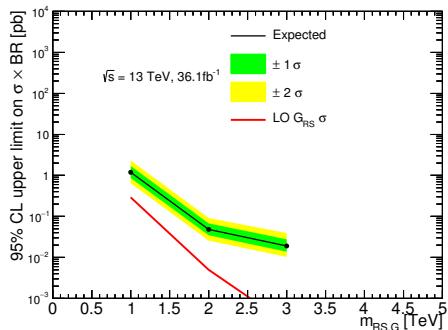

Figure 112: Extracted upper limits on Z' with no systematic uncertainty

Resulting expected upper limits on production cross section of Z' signal is shown in Fig. 113. Those for the RS graviton signal and KK gluon signal are also shown.

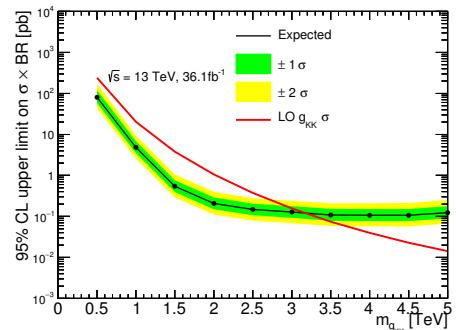

Using a benchmark of BSM signal, Z' , we expect upper limits on the production cross section of the Z' to be greater than 3.1 TeV. In addition, we also expect g_{KK} upper limits on the production cross section of the g_{KK} to be greater than 3.2 TeV.

(a) Upper limits on $\sigma_{Z'}$

(b) Upper limits on $\sigma_{RS\text{graviton}}$

(c) Upper limits on $\sigma_{KK\text{gluon}}$

Figure 113: Extracted upper limits on Z' , RS graviton and KK gluon production cross section.

10. Conclusions

In summary, we performed a search for resonances decaying into top and anti-top pair using all hadronic final state from data collected by the ATLAS detector at LHC. This analysis focuses on high mass signal, and the sensitivity is improved by combining several categories. Using a benchmark of BSM signal, Z' , we expect upper limits on the production cross section of the Z' to be greater than 3.1 TeV, which significantly improves the past results in ATLAS. In addition, we also expect g_{KK} upper limits on the production cross section of the g_{KK} to be greater than 3.2 TeV.

Appendix

A. Results without liner function fit to estimate some systematic uncertainties

Some systematic uncertainties are estimated to fit a liner function, because those systematics are affected statistical fractuation for low statistics. Each systematic uncertainty is checked in each subsection, and estimated uncertainties are used to estimate the cross section with SR0+SR3 and to compare with the nominal result.

A.1. $t\bar{t}$ B-tagging

The mtt distributions for the systematic samples are compared with the nominal samples as can be found in Fig. 114-118. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

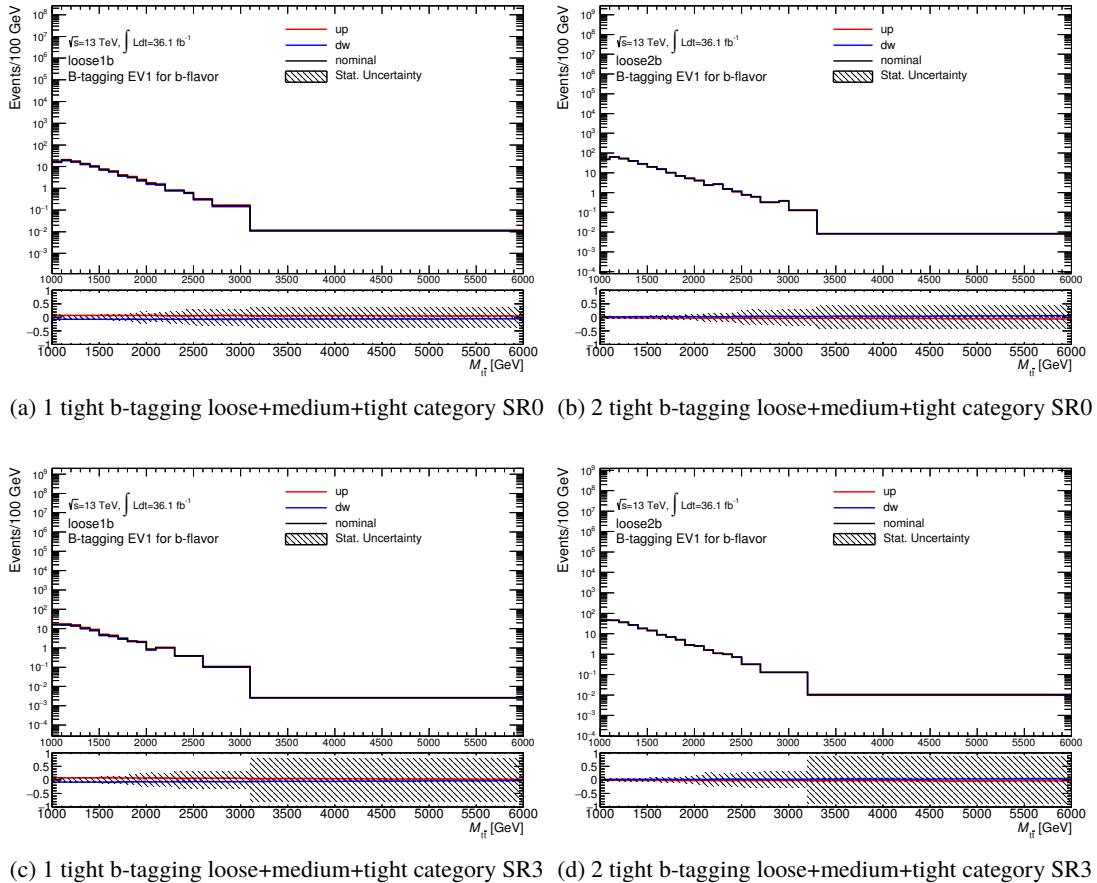

Figure 114: Systematics of B-tagging EV 1 of b-flavor for $t\bar{t}$

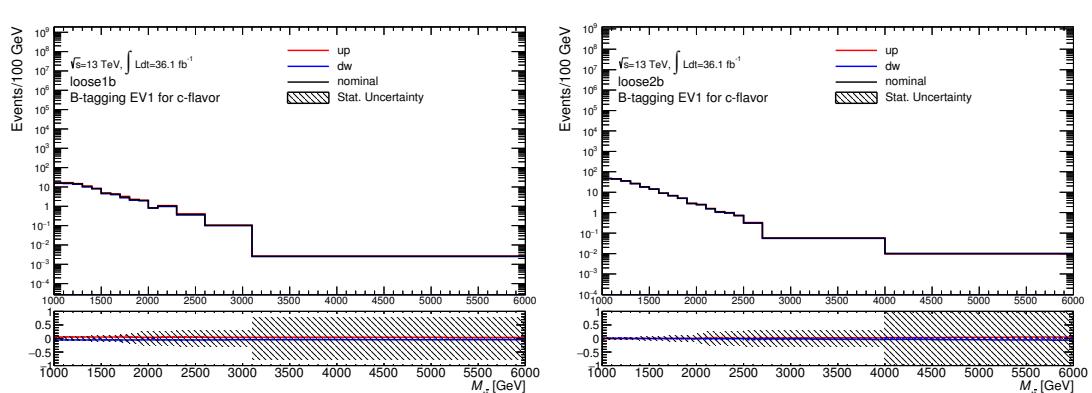

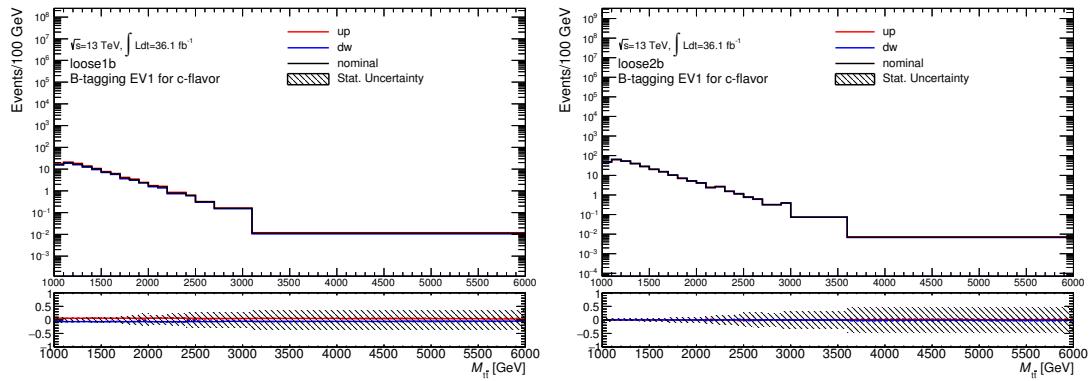

Figure 115: Systematics of B-tagging EV 1 of c-flavor for $t\bar{t}$

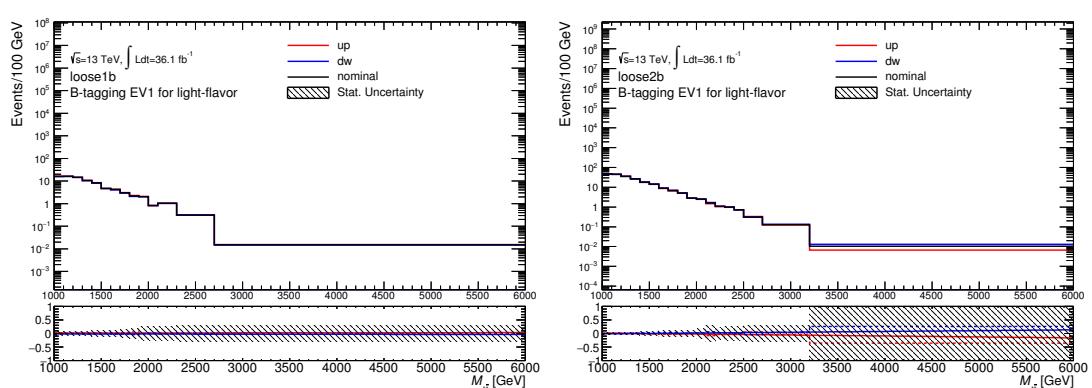

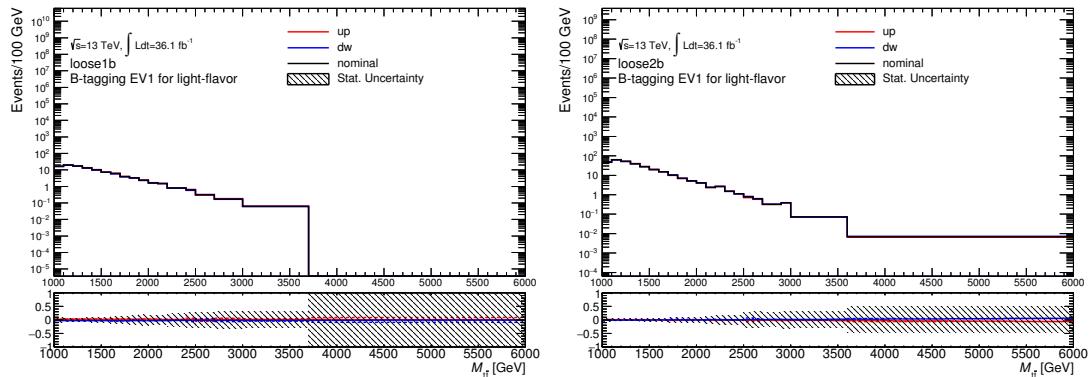

Figure 116: Systematics of B-tagging EV 1 of light-flavor for $t\bar{t}$

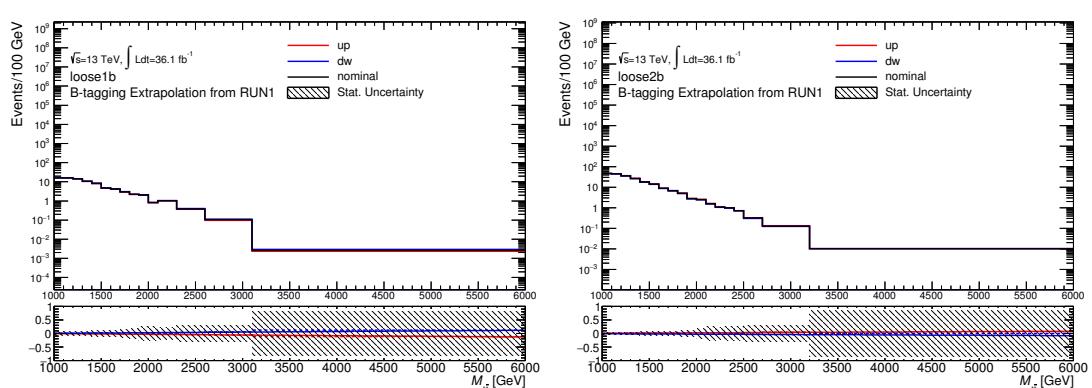

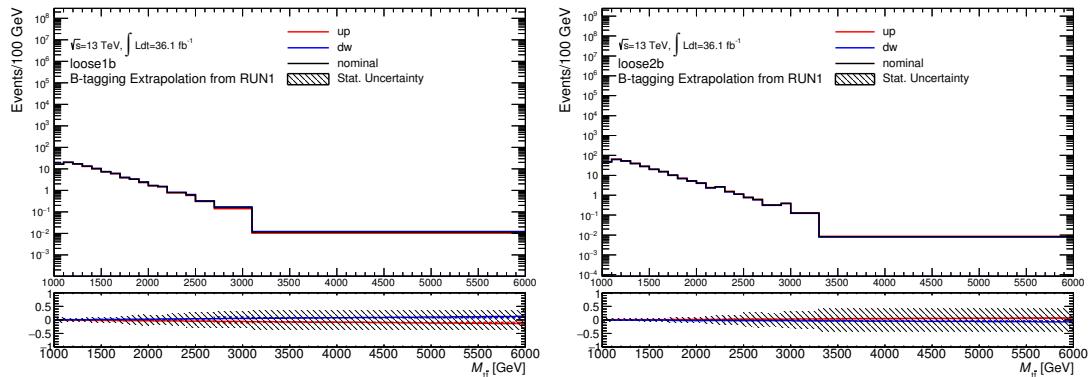

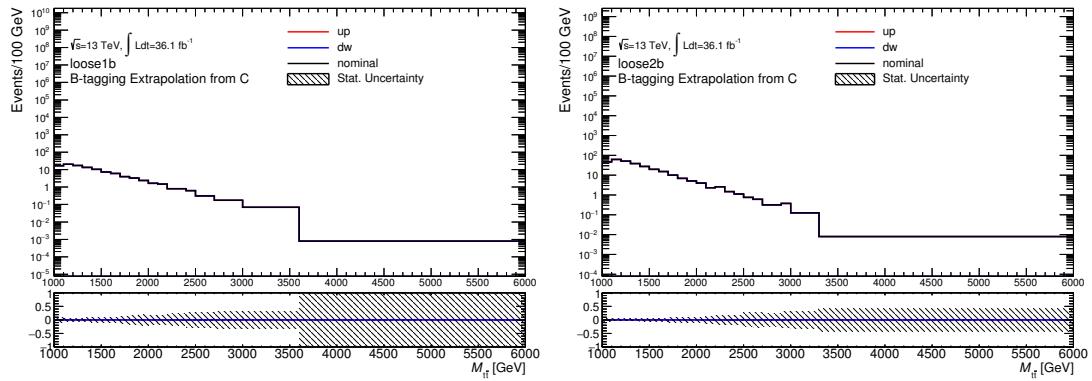

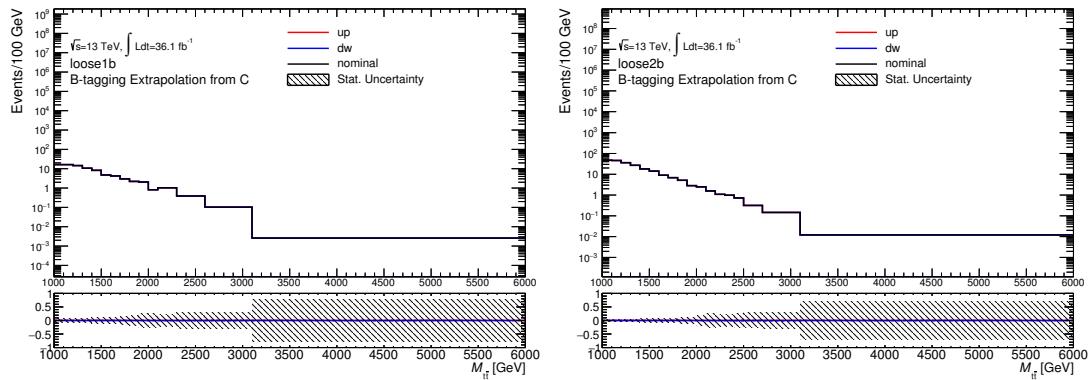

Figure 117: Systematics of B-tagging Extrapolation from RUN1 for $t\bar{t}$

(c) 1 tight b-tagging loose+medium+tight category SR3 (d) 2 tight b-tagging loose+medium+tight category SR3

Figure 118: Systematics of B-tagging Extrapolation from c-tagging for $t\bar{t}$

A.2. $t\bar{t}$ Large-R jet uncertainty

Systematic varied distributions and nominal distributions are compared to in Fig. 119-125. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

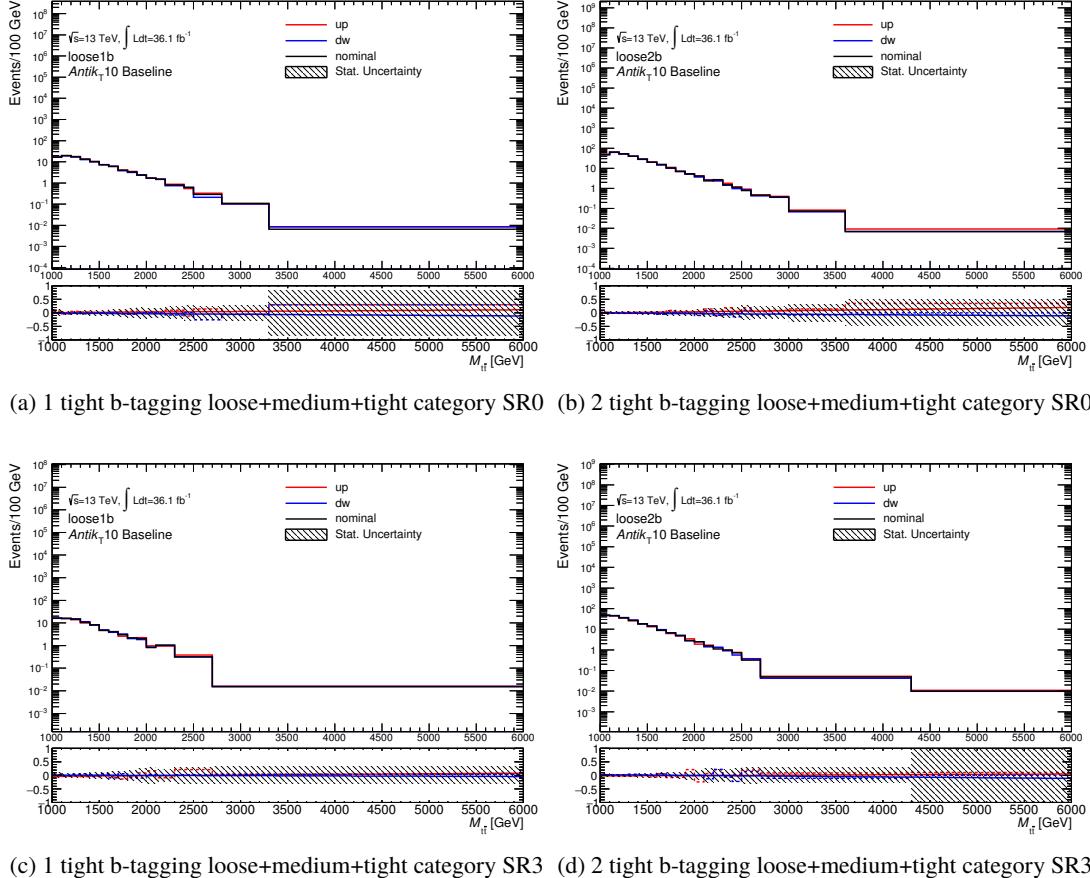

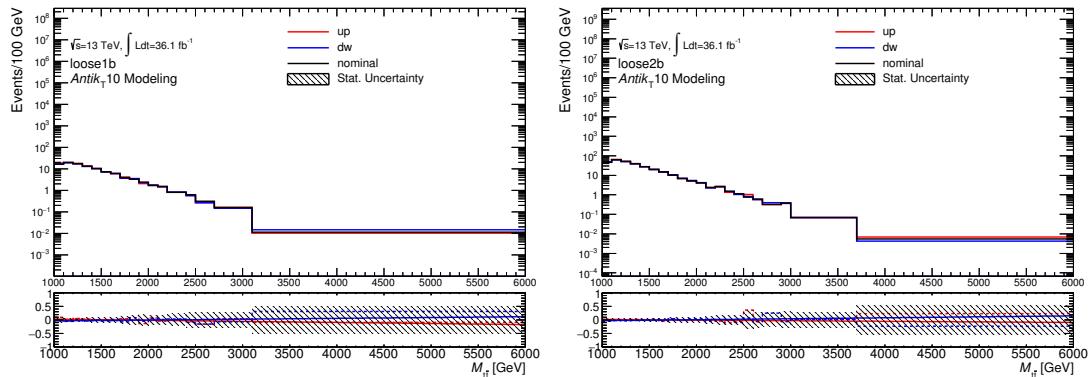

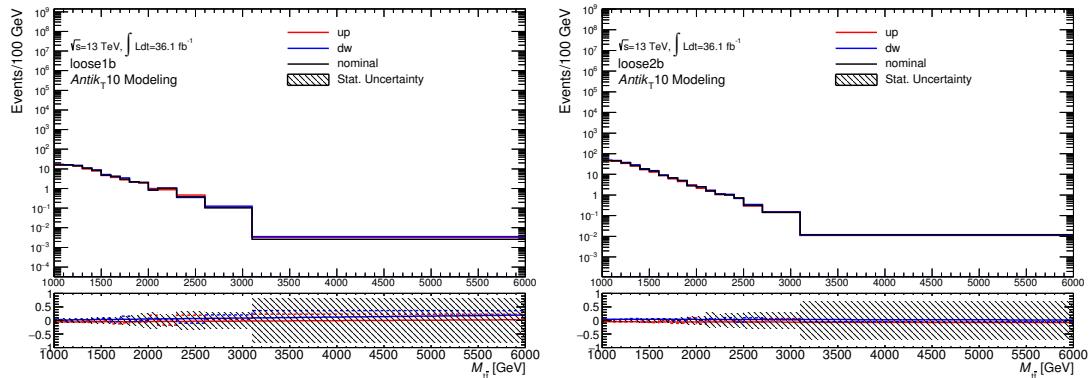

Figure 119: Systematics of Large-R jet baseline for $t\bar{t}$

Figure 125: Systematics of Large-R jet τ_{32}^{wta} resolution for $t\bar{t}$

A.3. $t\bar{t}$ electroweak correction

Systematic varied distributions and nominal distribtuions are compared to in Fig. 126. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

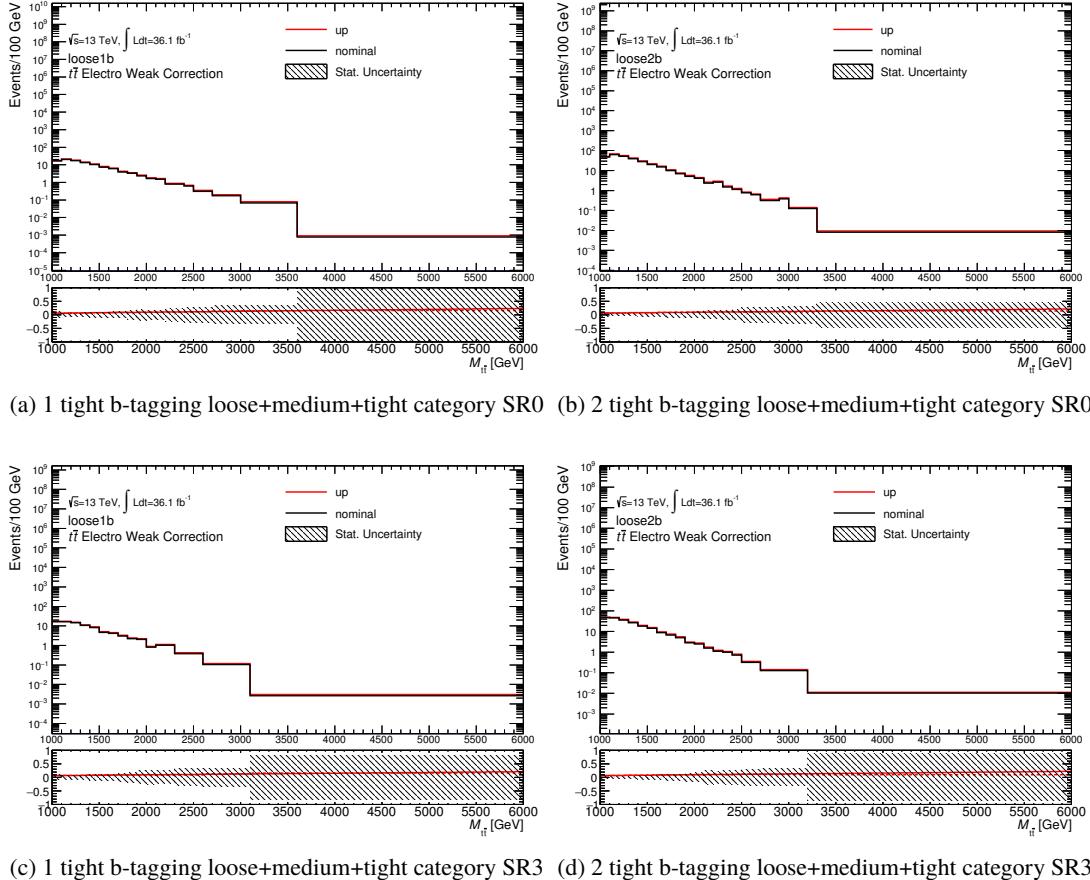

Figure 126: Systematics of electroweak correction for $t\bar{t}$

A.4. $t\bar{t}$ generator

Systematic varied distributions and nominal distribtuions are compared to in Fig. 127. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

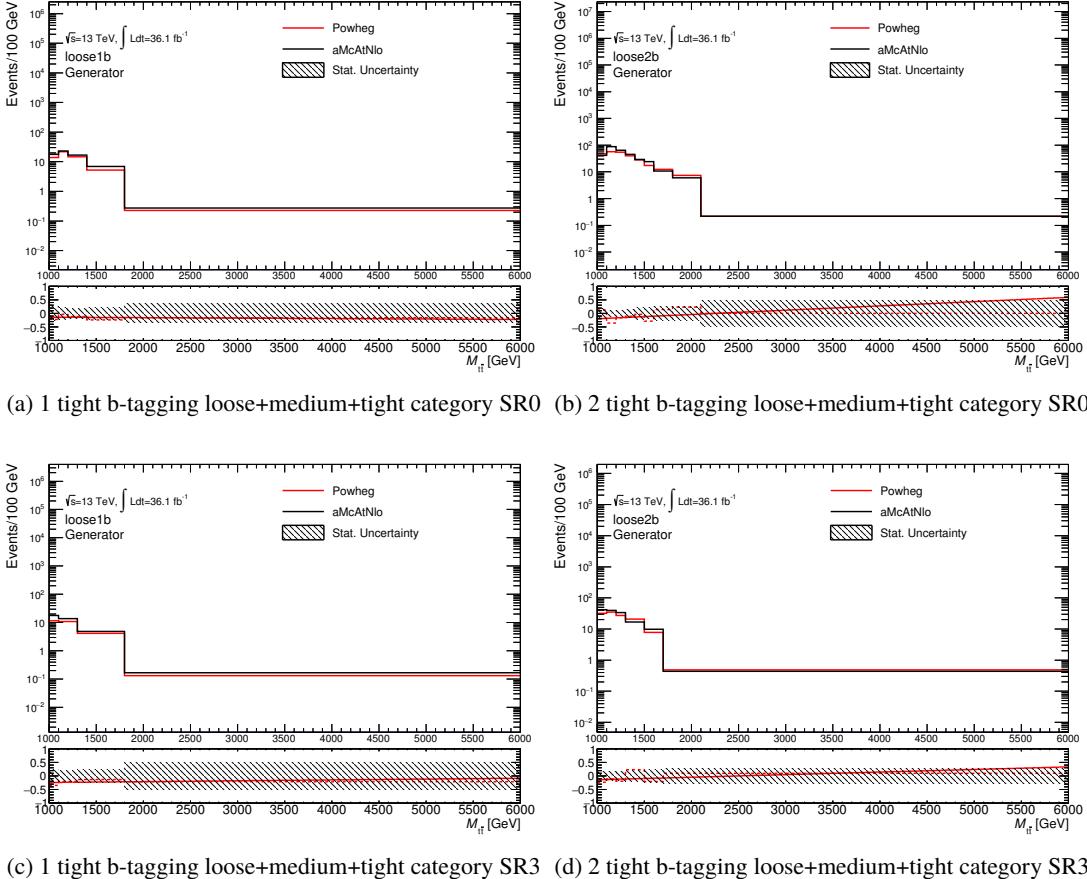

Figure 127: Systematics of generator for $t\bar{t}$

A.5. $t\bar{t}$ parton shower model

Systematic varied distributions and nominal distributions are compared to in Fig. 128. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

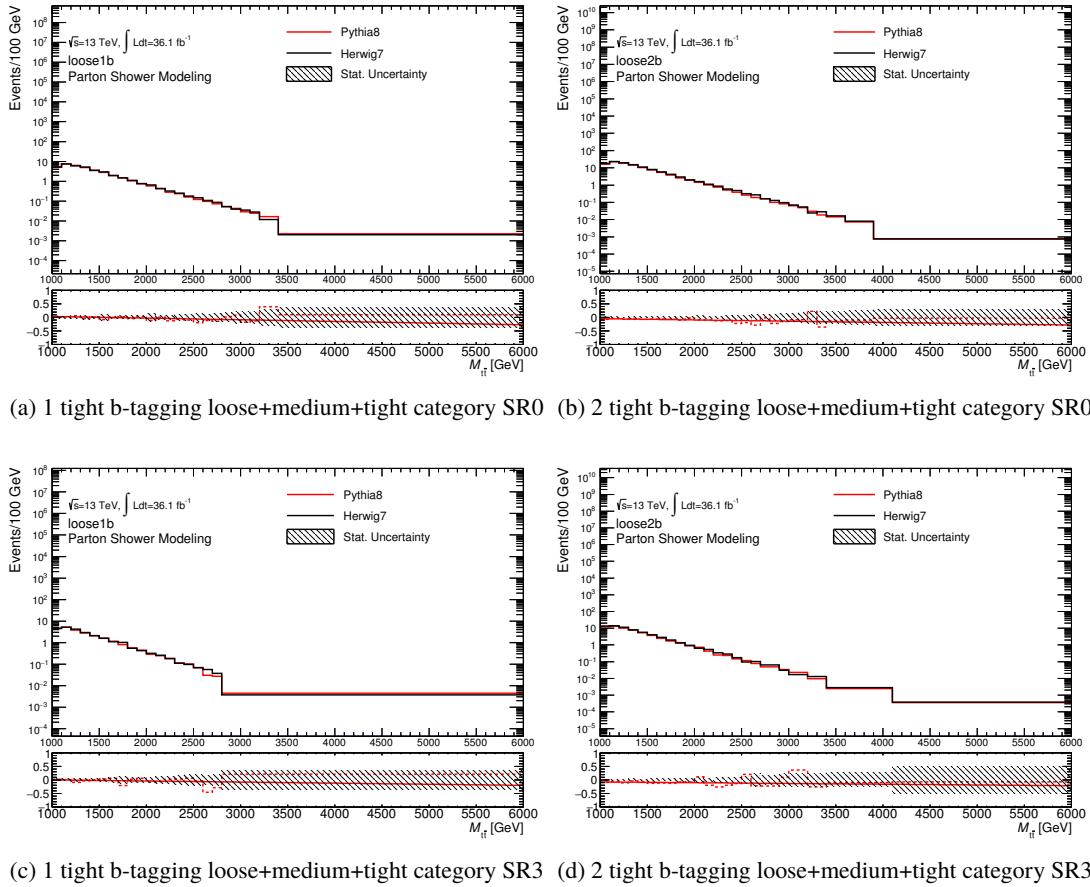

Figure 128: Systematics of parton shower for $t\bar{t}$

A.6. $t\bar{t}$ ISR/FSR

Systematic varied distributions and nominal distributions are compared to in Fig. 129. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

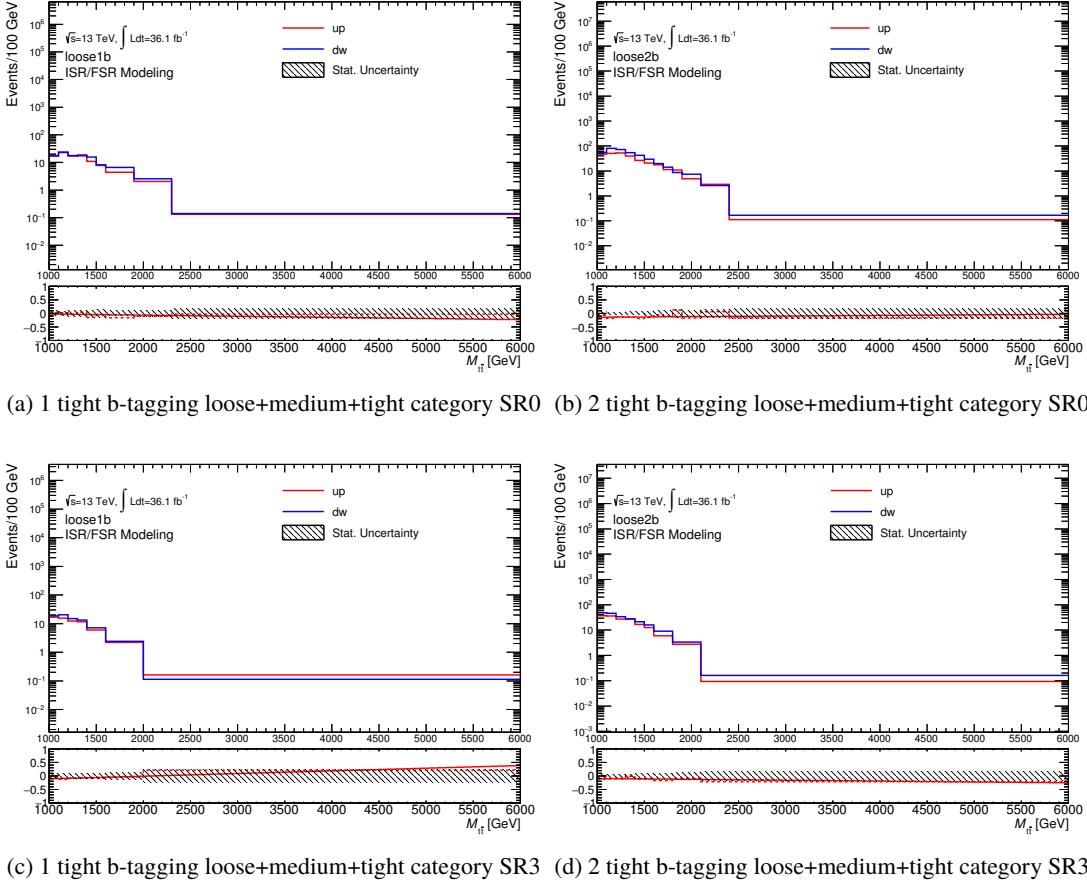

Figure 129: Systematics of ISR/FSR for $t\bar{t}$

A.7. $t\bar{t}$ PDF

Systematic varied distributions and nominal distributions are compared to in Fig. 130. All the systematic uncertainties before the linear fit are smaller than the statistic uncertainty.

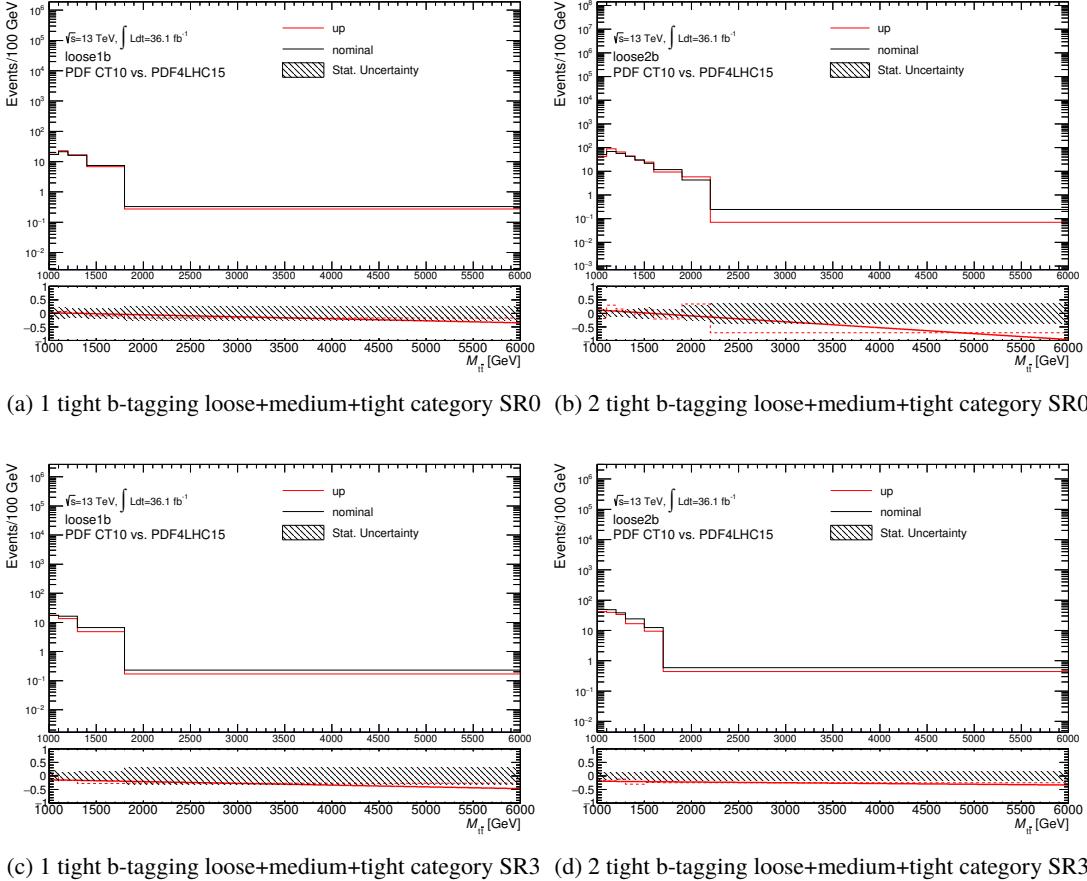

Figure 130: Systematics of PDF for $t\bar{t}$

A.8. The result without liner fit to estimate systematic uncertainty

Conditions are same as nominal except for some systematic uncertainties which are estimated without liner fit. Nuisance parameter pulls are showed in Fig. 131.

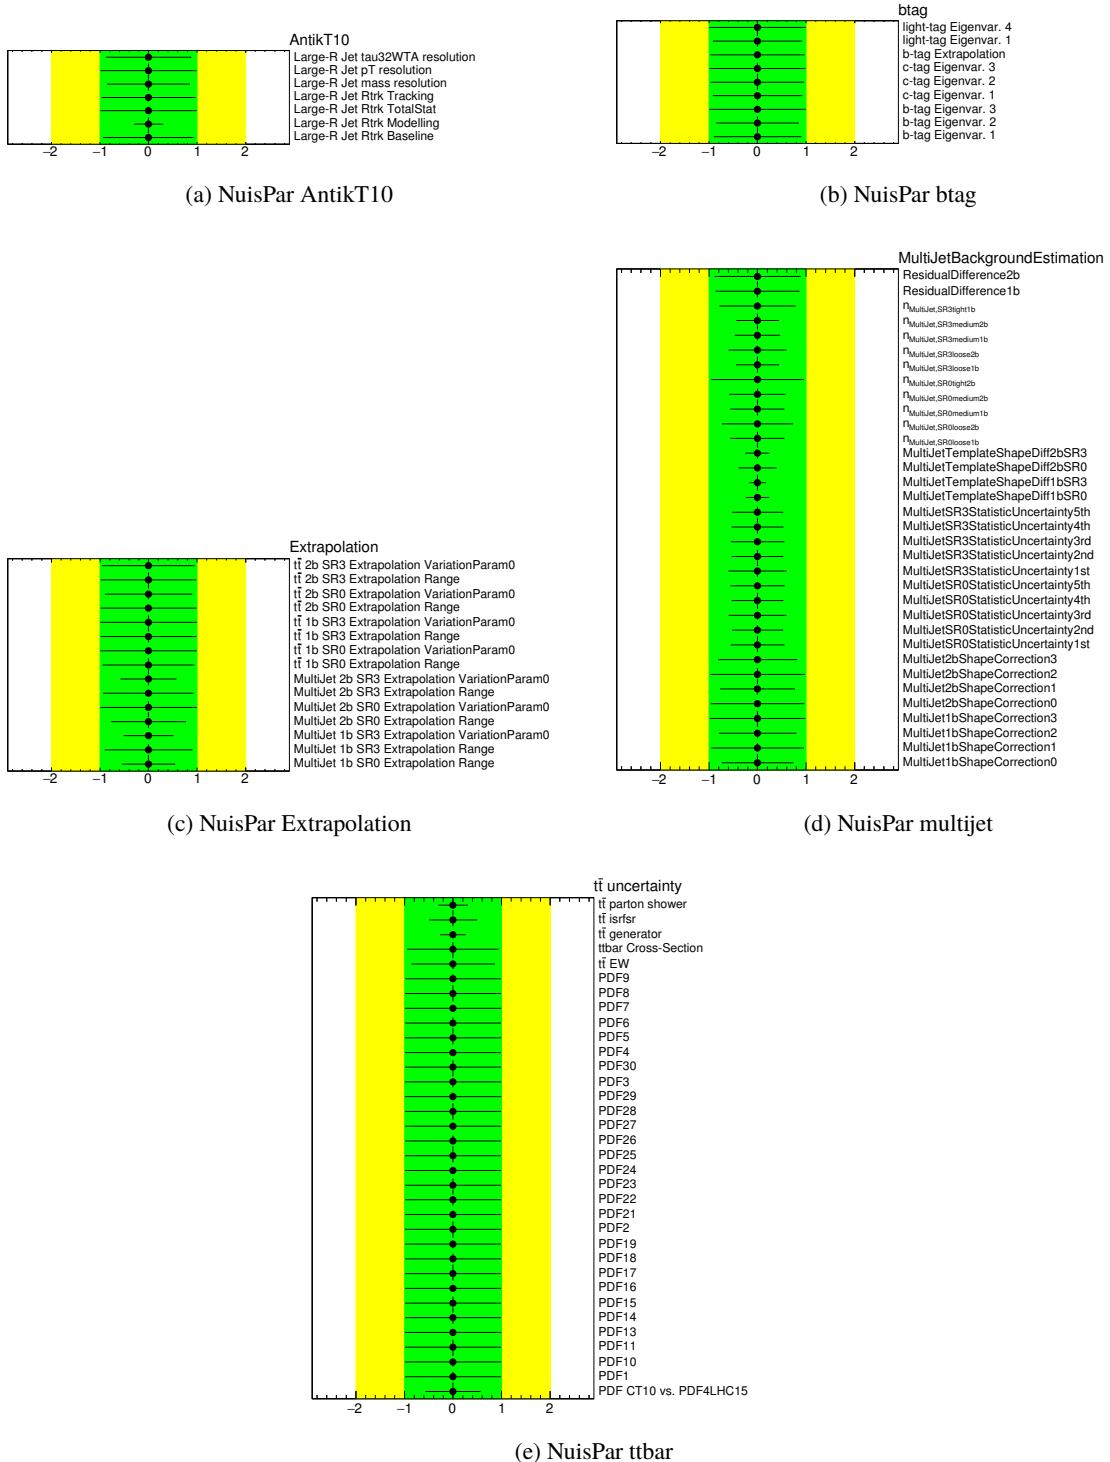

Figure 131: Nuisance parameters for the fitting.

Correlation matrix are showed in Fig. 132.

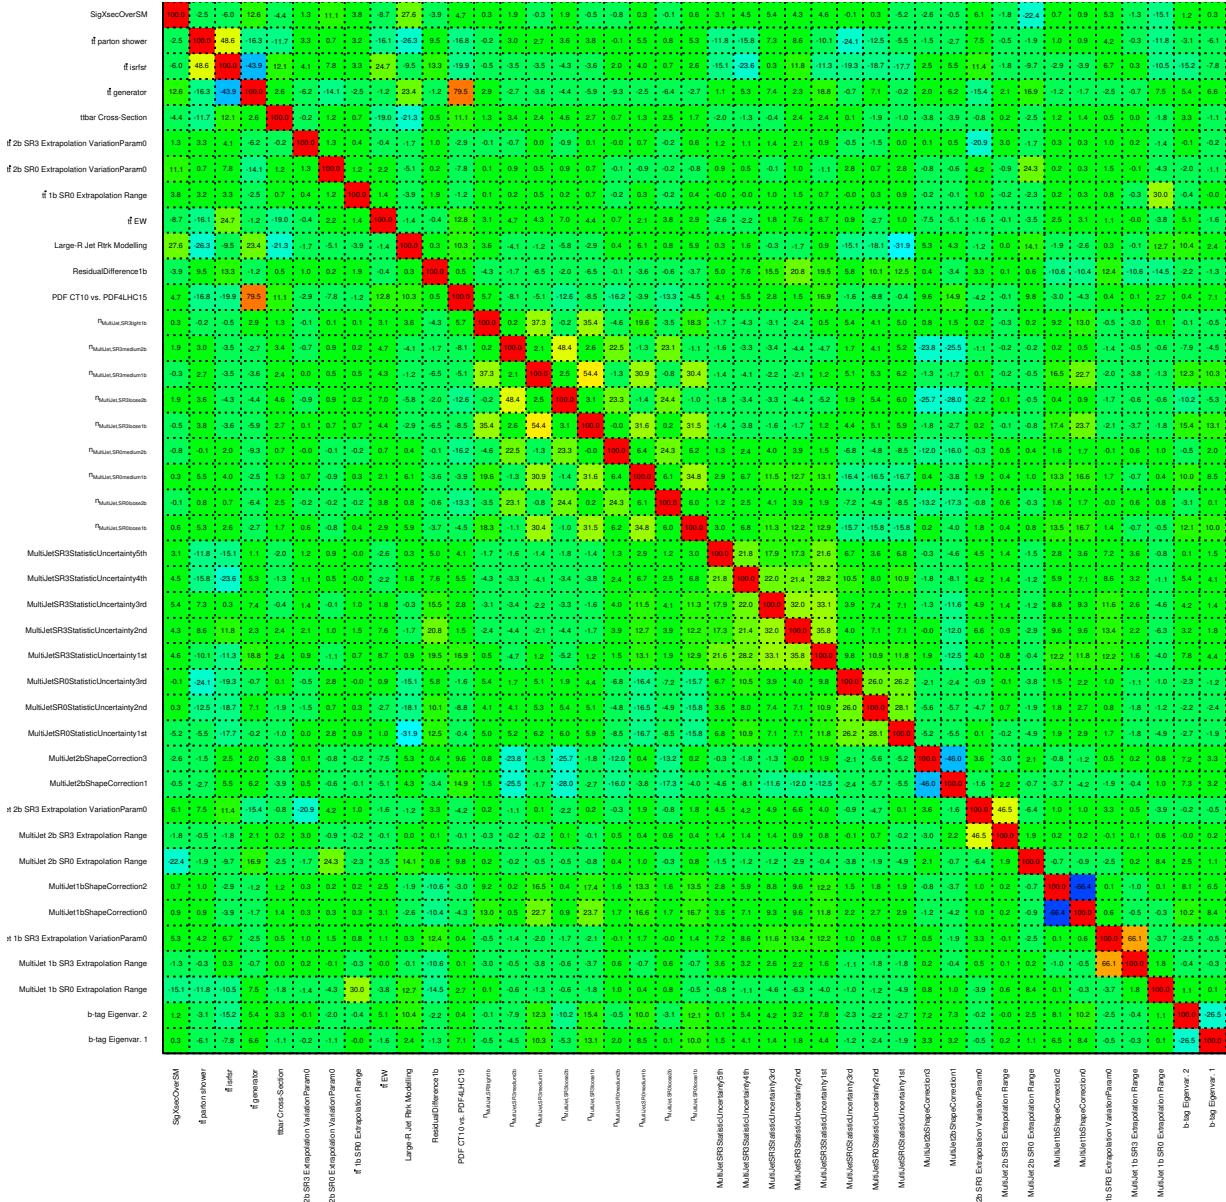

Figure 132: Correlation matrix (Showed nuisance parameters have correlation value over 20%).

Pre-fit and Post-fit $m_{t\bar{t}}$ distributions are showed in Fig. 133, 134 135 and 136.

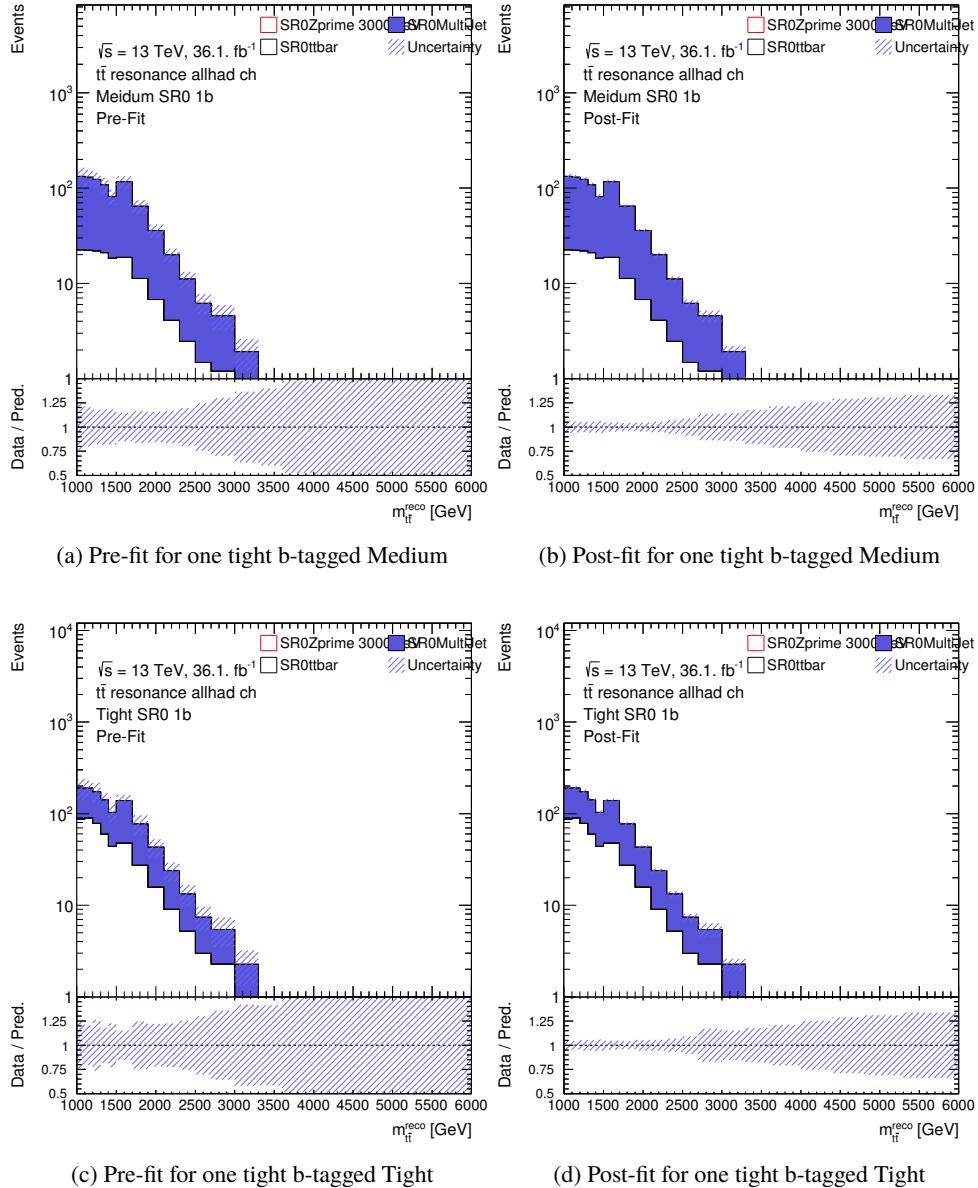

Figure 133: Pre-fit and Post-fit distributions for one tight b-tagged SR0

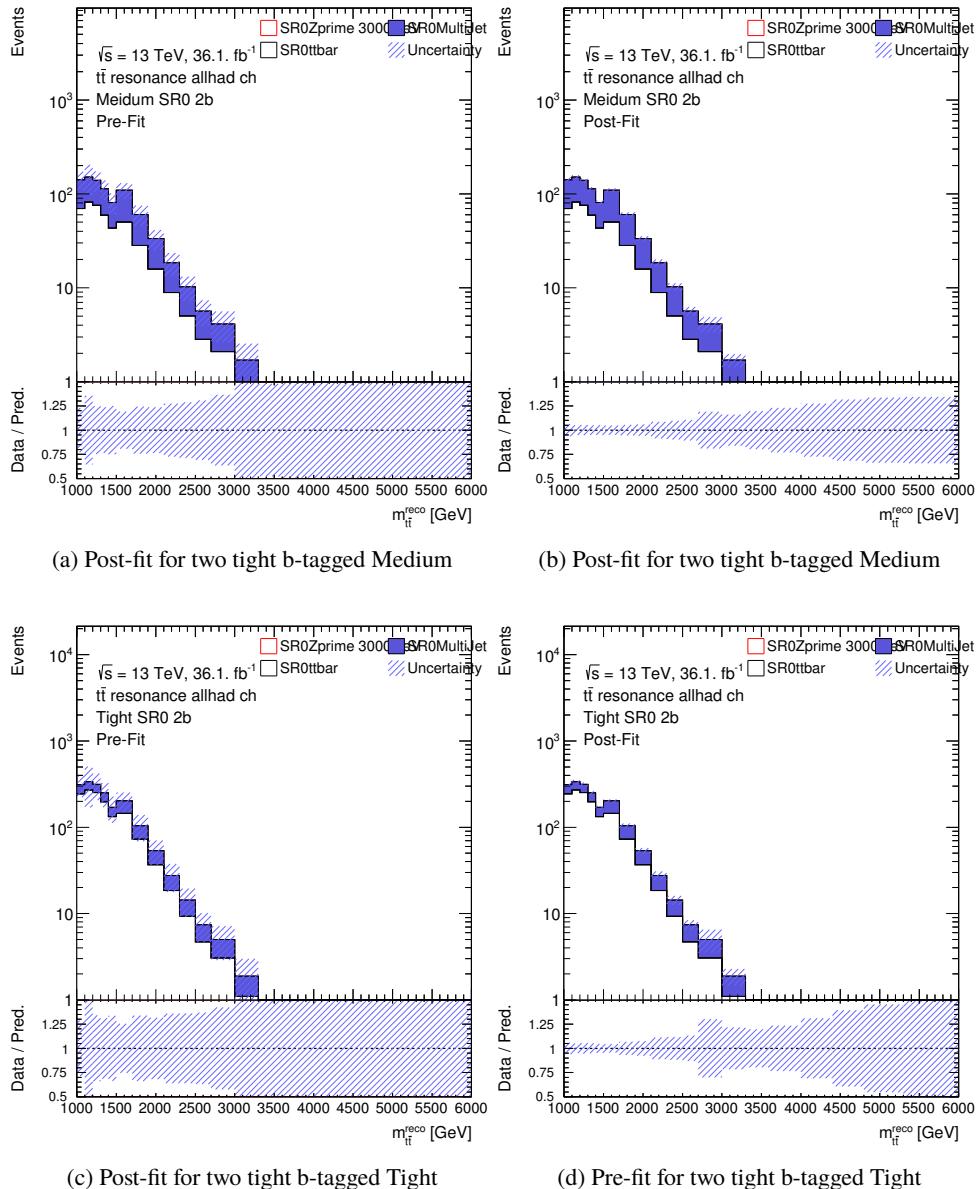

Figure 134: Pre-fit and Post-fit distributions for two tight b-tagged SR0

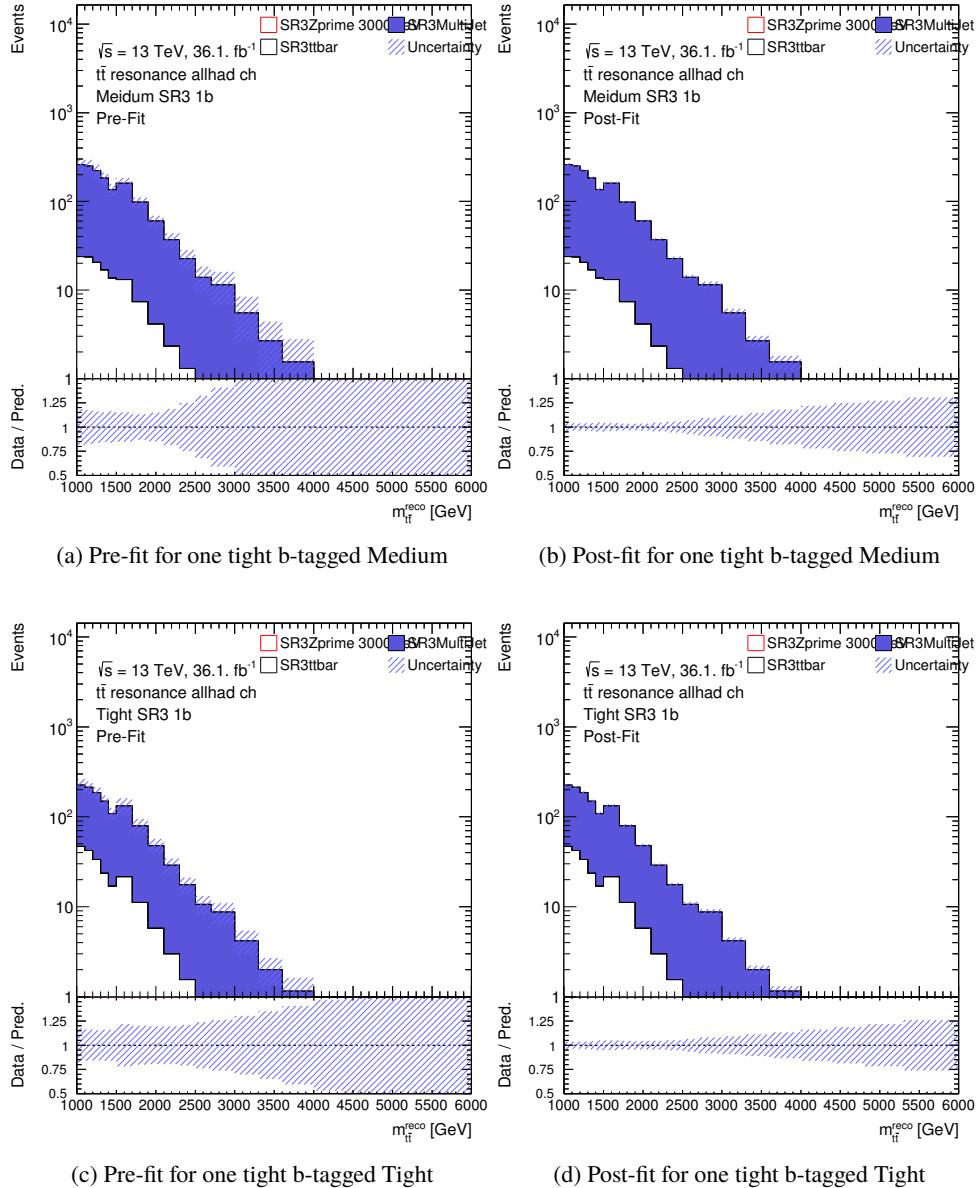

Figure 135: Pre-fit and Post-fit distributions for one tight b-tagged SR3

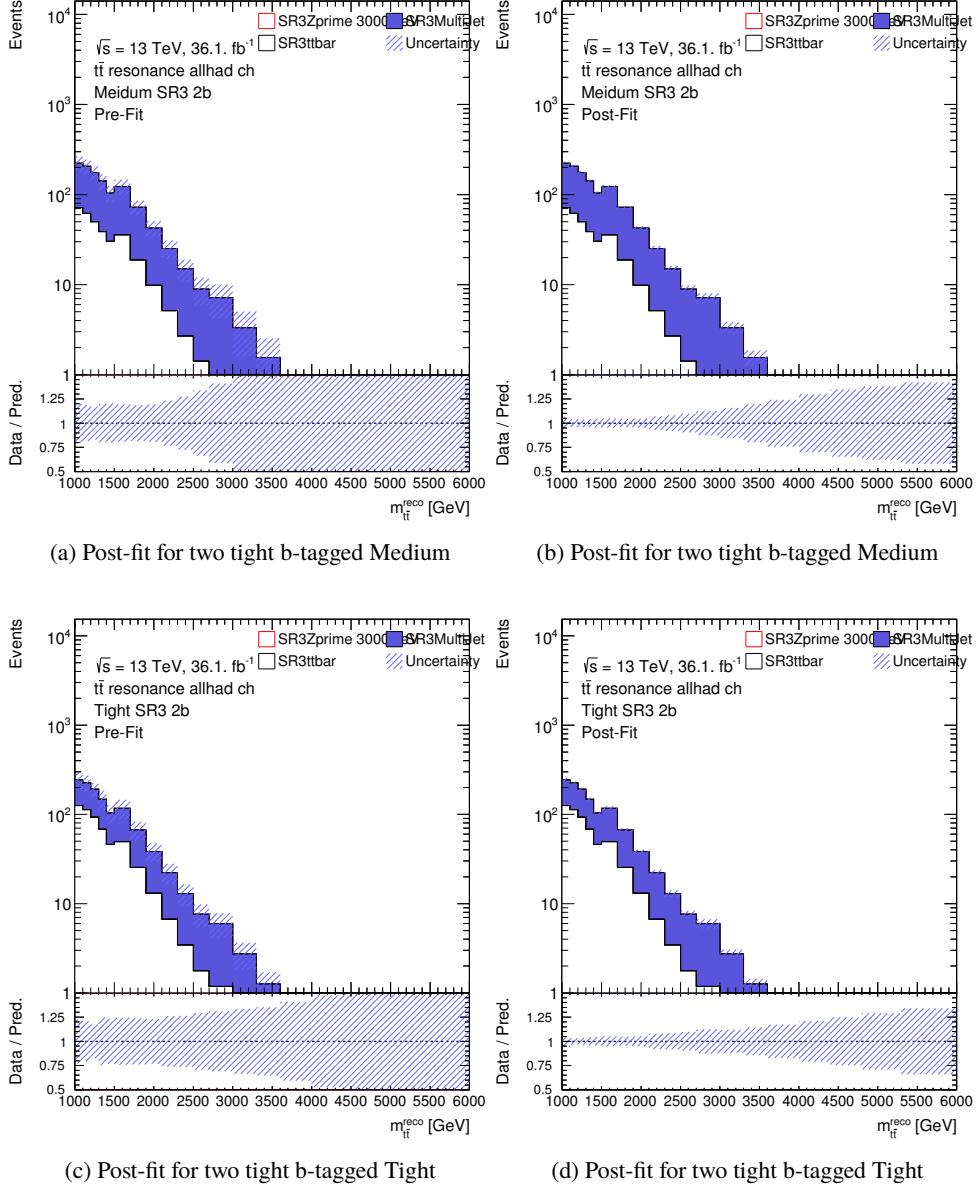

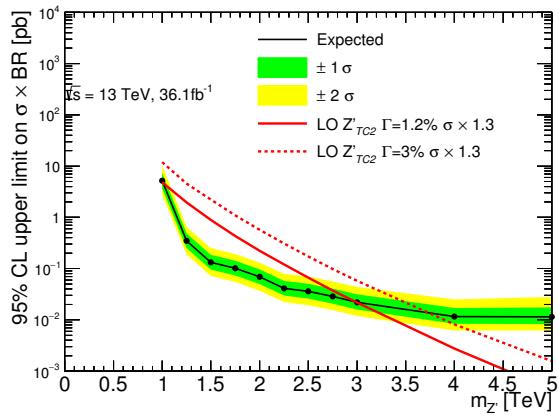

Figure 136: Pre-fit and Post-fit distributions for two tight b-tagged SR3

Fit result is showed in Fig. 137. Comarison of cross section limits between nominal and without liner fit to estimate systematic uncertainties is summarized in Table 18. The higher masss limit are worse if systematic uncertainties are estimated without liner fit, because higher mass bins are low statistics and cover wide $m_{t\bar{t}}$ region. Therefore systematic uncertainties are reasonablly estimated with liner fit to estimate them.

C. signal injection test with psedo data

The pseudo-asimov data sets are created with the estimated background and the Z' signal with mass $m_{Z'} = 1$ TeV, 2 TeV, 3 TeV. In addition the pseudo-asimov data is smeared with a Poisson distribution. Background only and signal+background fits are performed with the pseudo-asimov data, $\mu = 2$ and SR0+SR3 regions.

Figures 138, 139 and 140 show the each nuisance parameter pull.

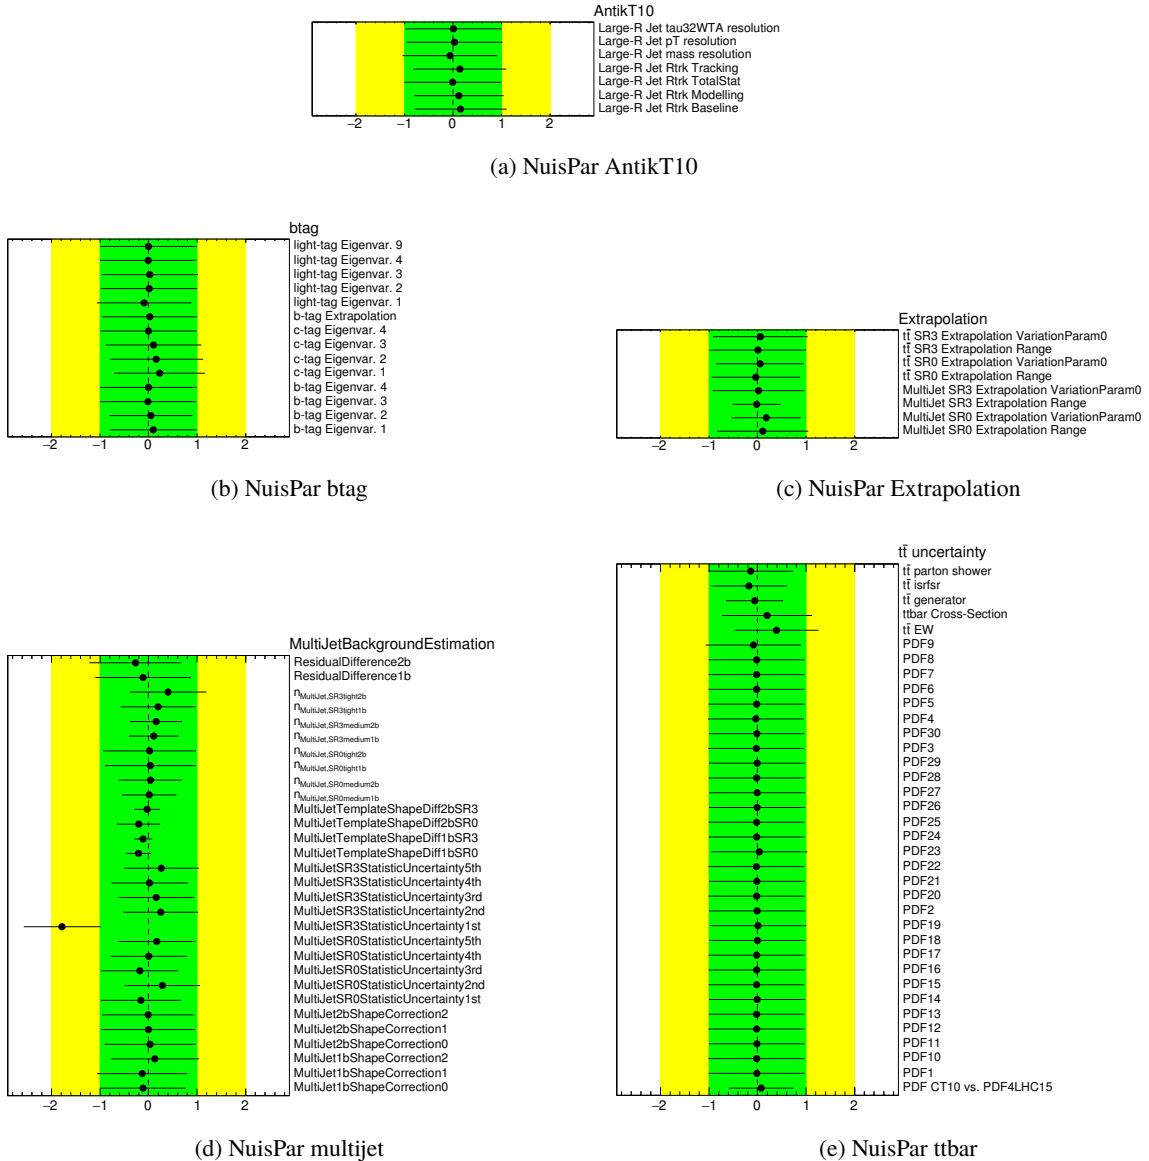

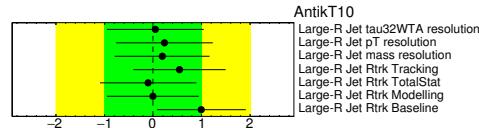

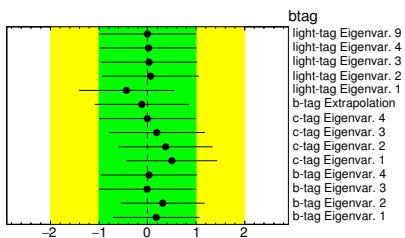

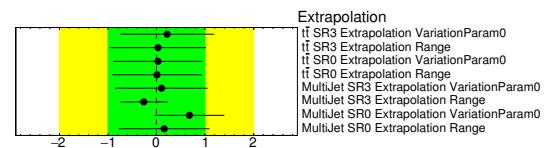

Figure 138: Nuisance parameter pulls for fitting with the pseudo date injected Z' 1 TeV

(b) NuisPar btag

(c) NuisPar Extrapolation

(d) NuisPar multijet

(e) NuisPar ttbar

Figure 139: Nuisance parameter pulls for fitting with the pseudo date injected Z' 2 TeV

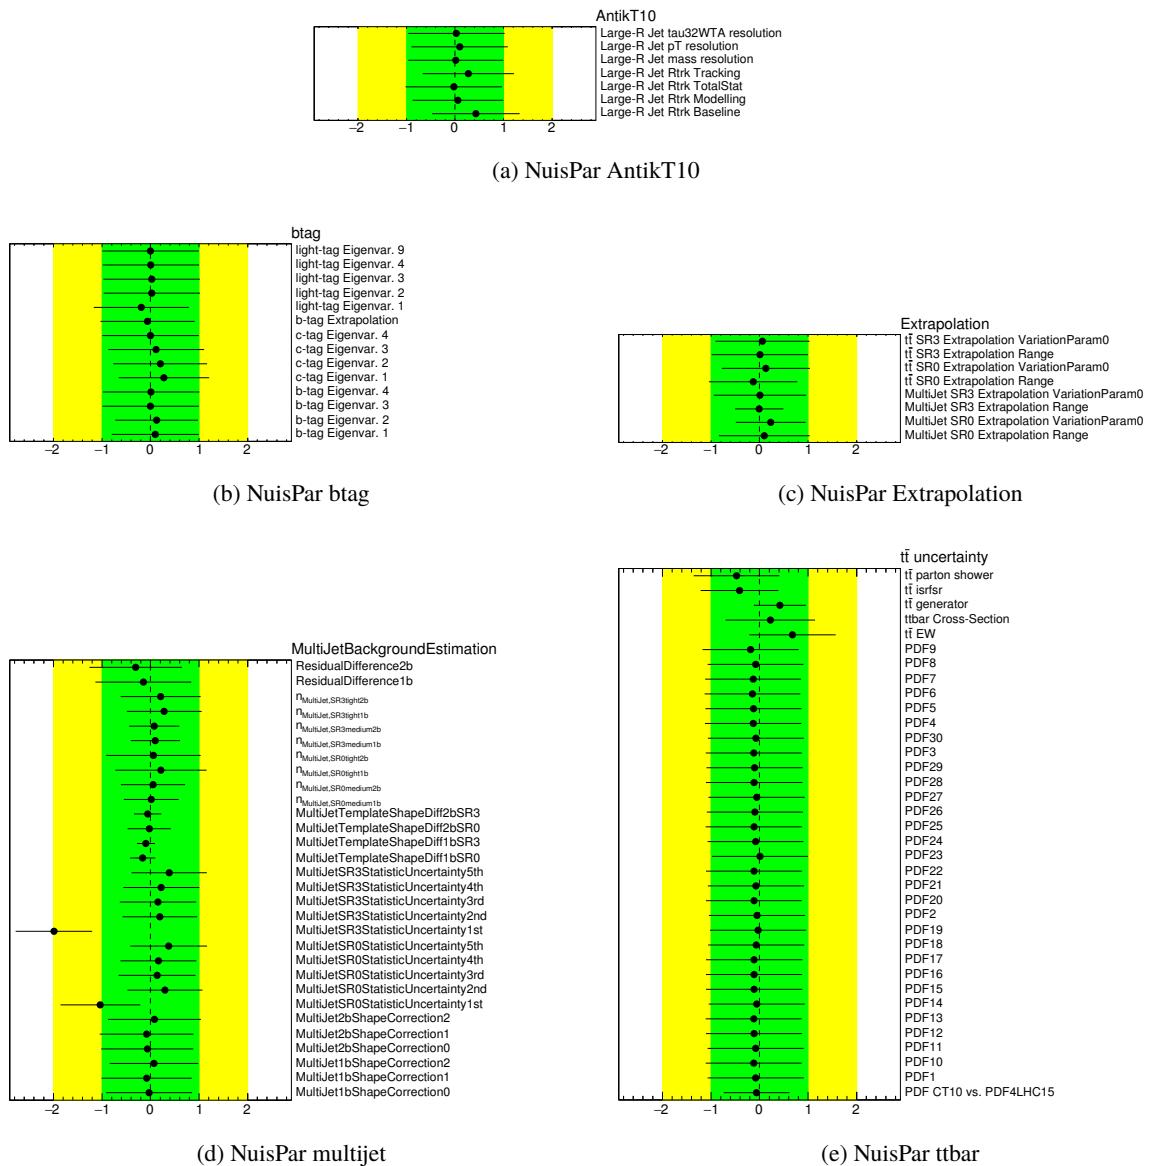

Figure 140: Nuisance parameter pulls for fitting with the pseudo date injected Z' 3 TeV

Pre-fit and Post-fit $m_{t\bar{t}}$ distributions are showed in Figure 141 and 142 for the pseudo-asimov data injected $Z' 1 \text{ TeV}$.

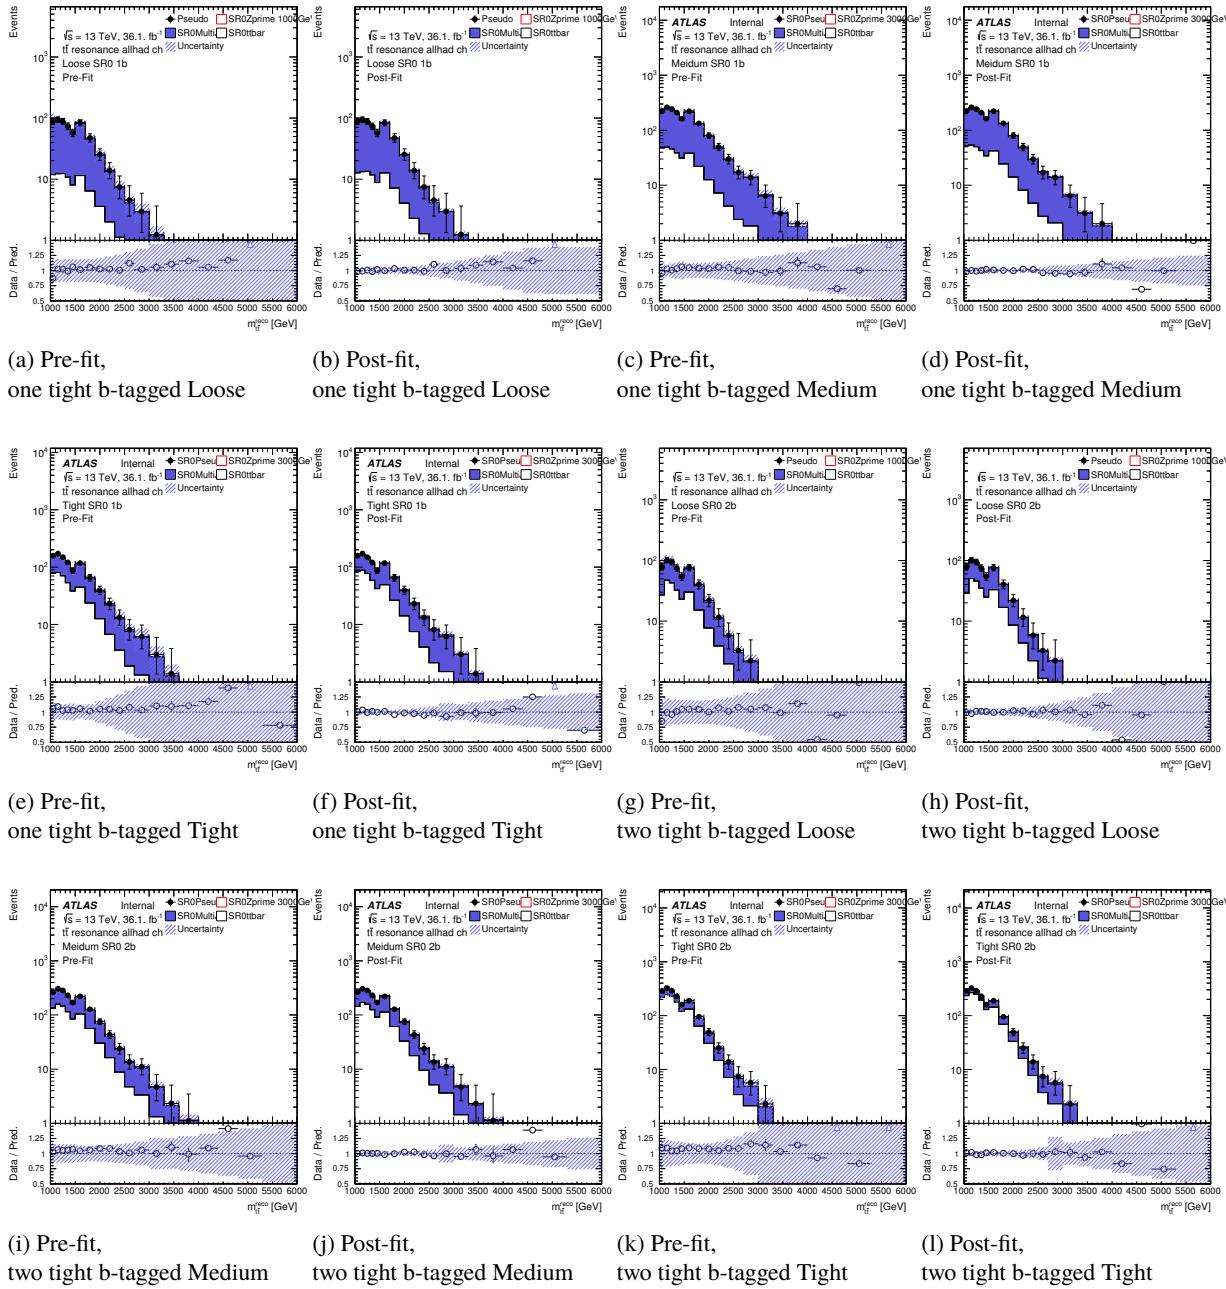

Figure 141: Pre-fit and Post-fit distributions for SR0 and the pseudo date injected Z' 1 TeV

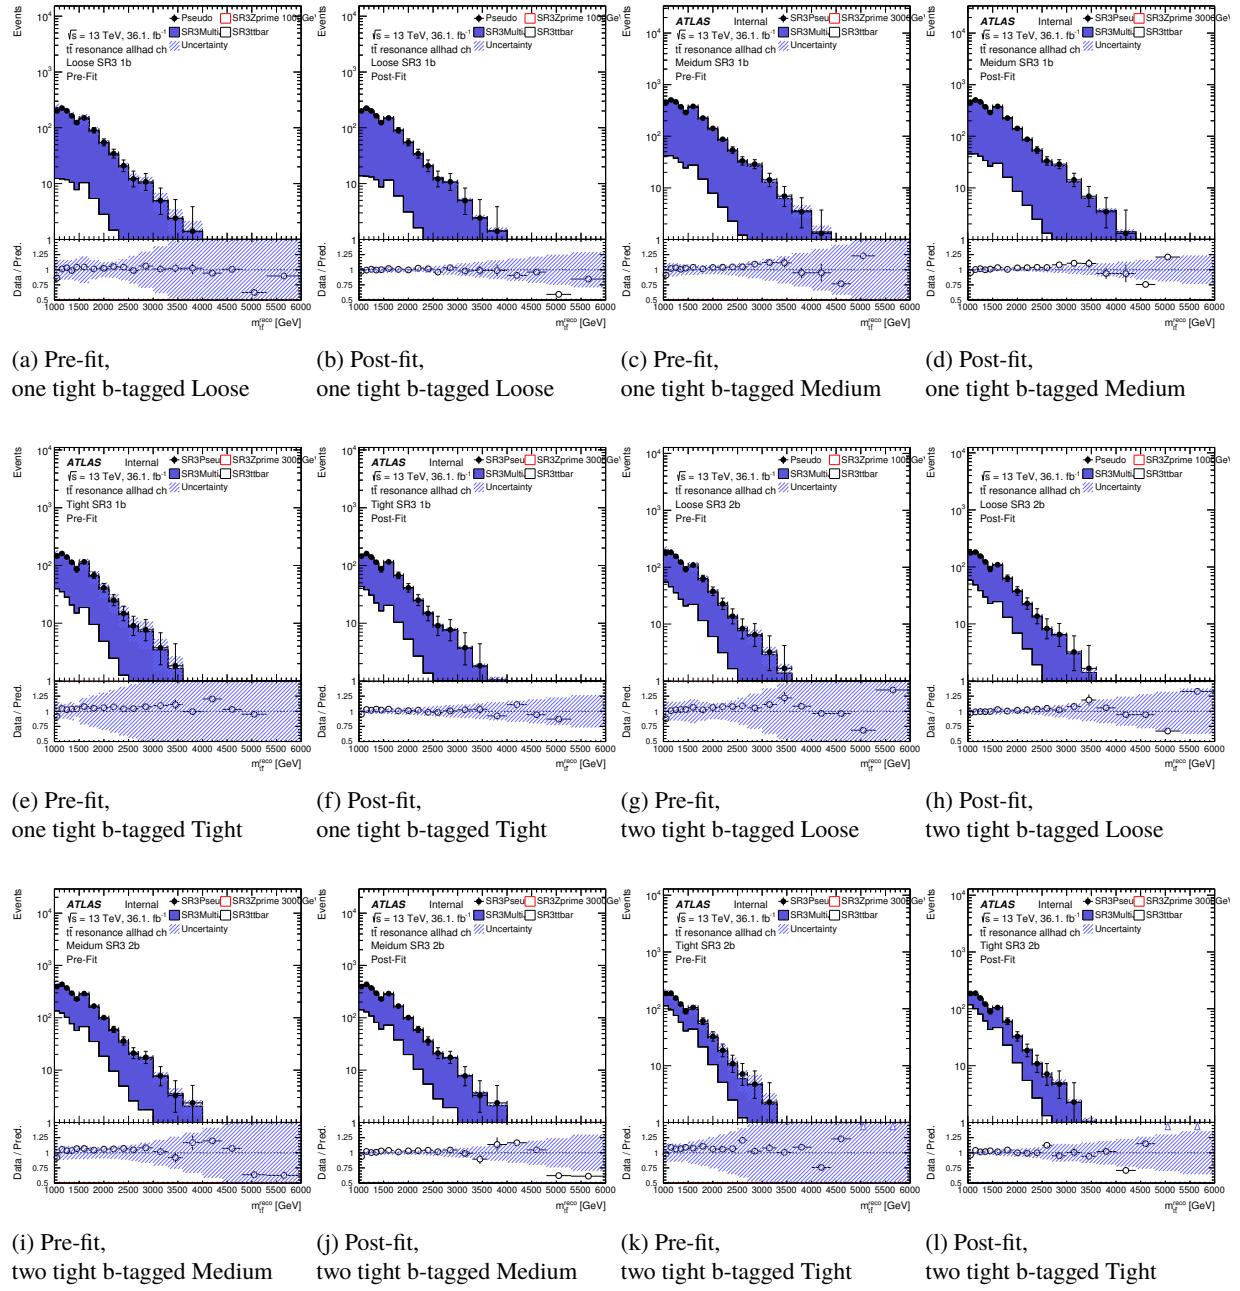

Figure 142: Pre-fit and Post-fit distributions for SR3 and the pseudo date injected Z' 1 TeV

For the pseudo-asimov data injected Z' 2 TeV, Pre-fit and Post-fit $m_{t\bar{t}}$ distributions are showed in Figure 143 and 144.

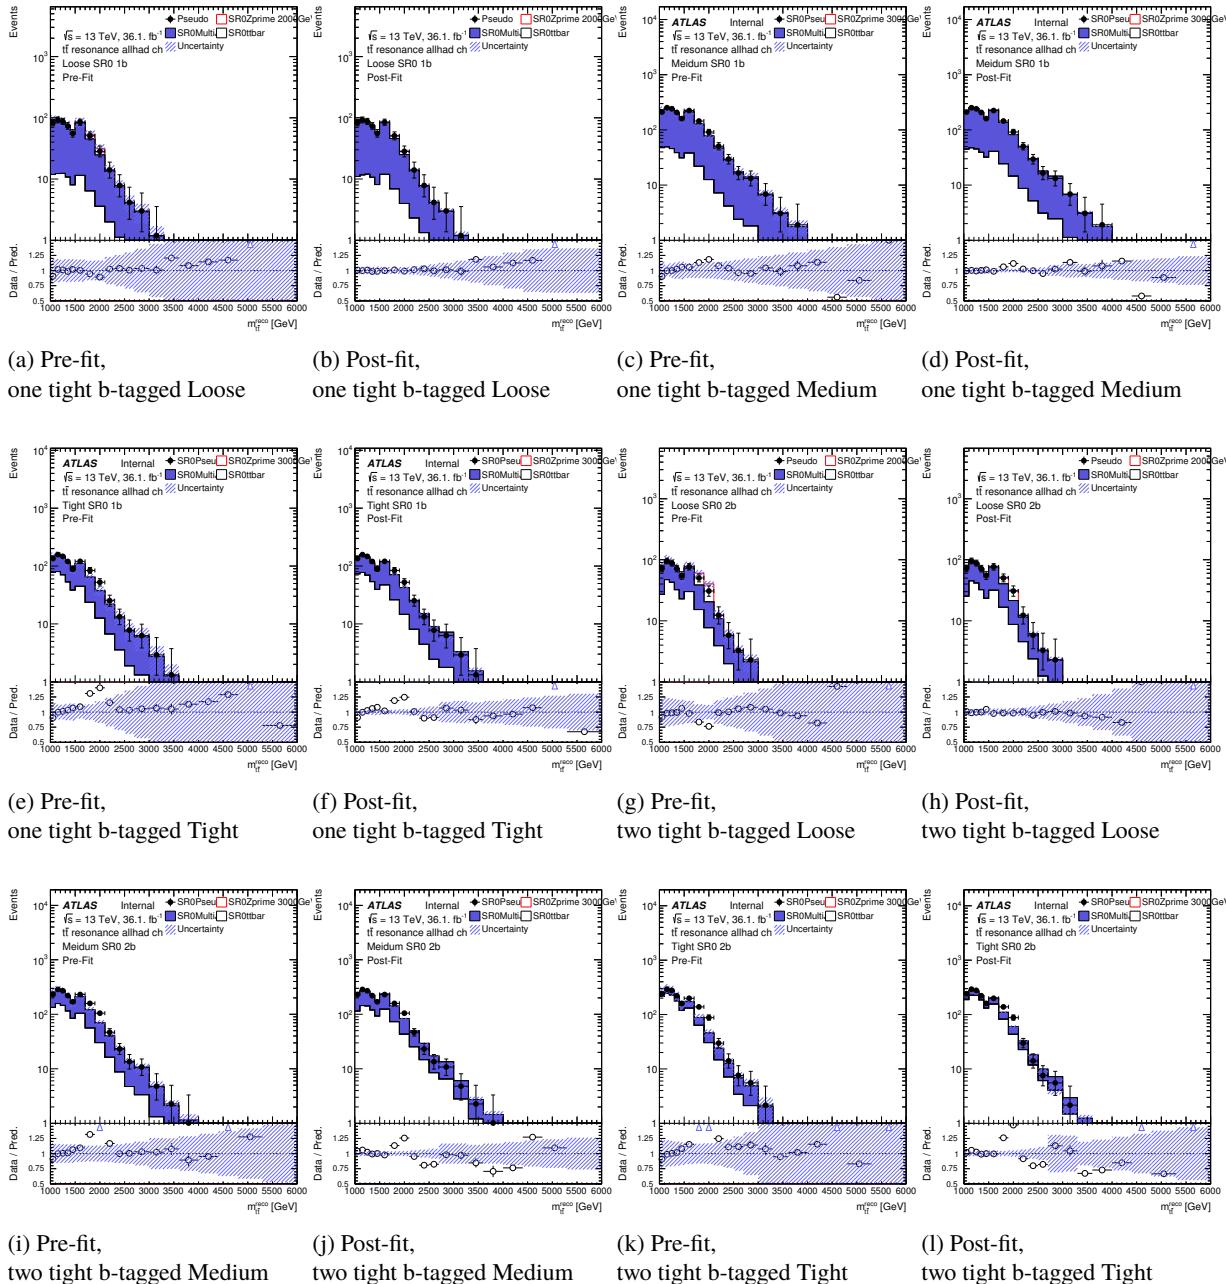

Figure 143: Pre-fit and Post-fit distributions for SR0 and the pseudo date injected Z' 2 TeV

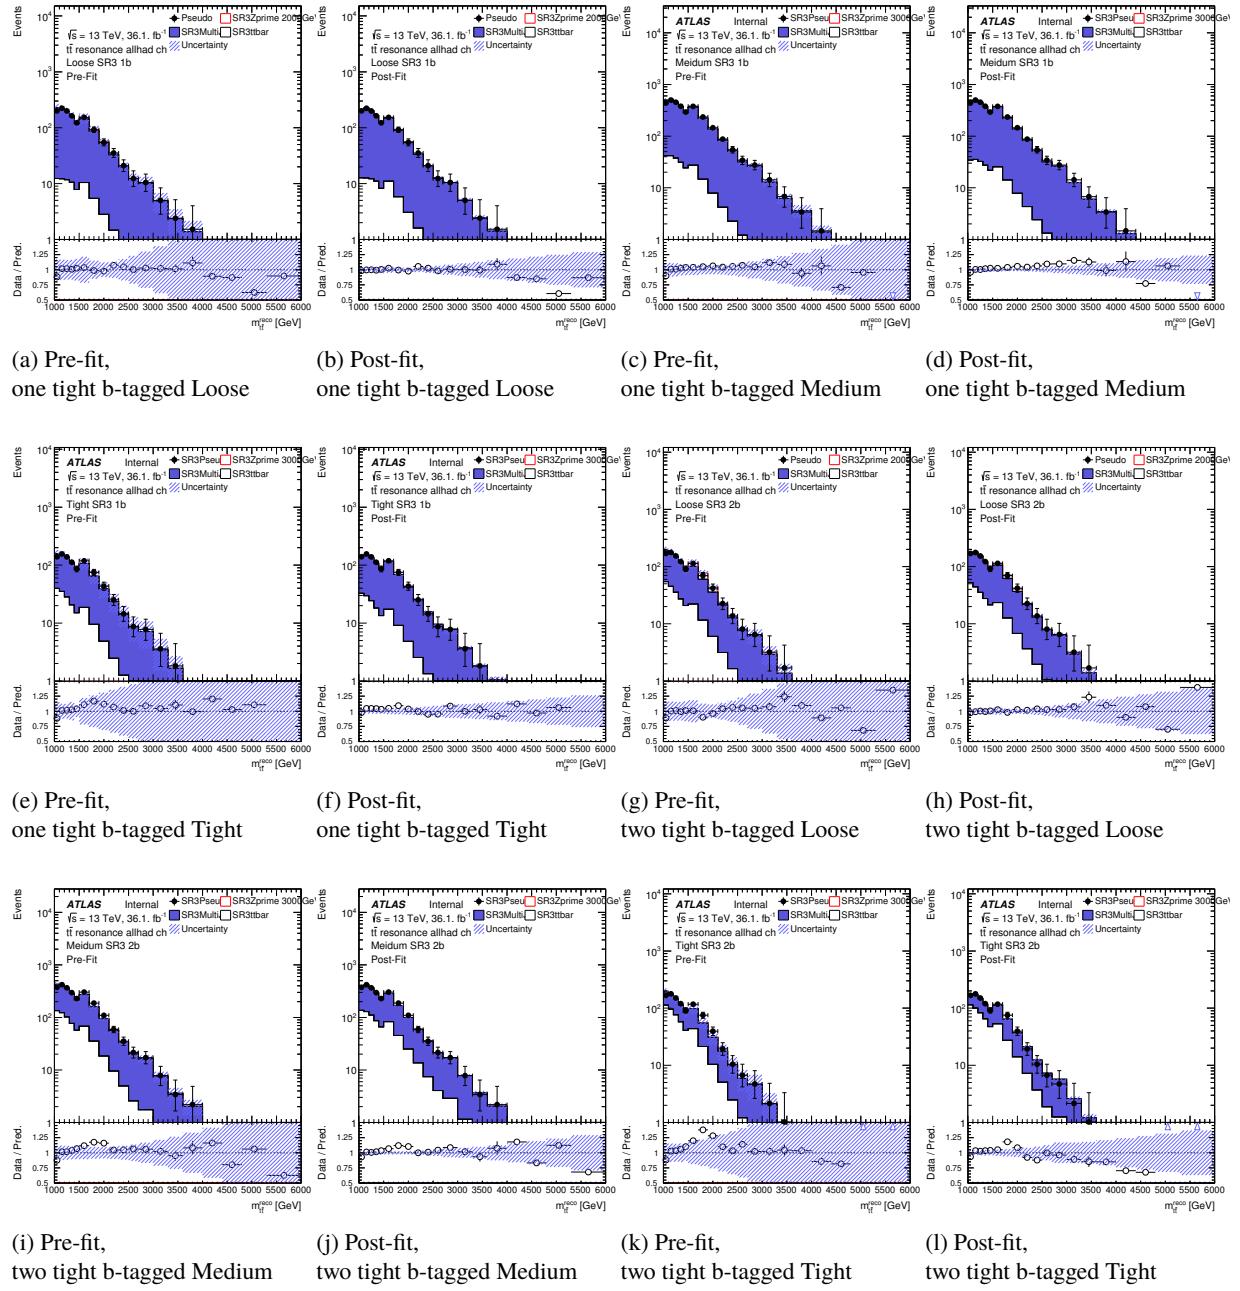

Figure 144: Pre-fit and Post-fit distributions for SR3 and the pseudo date injected Z' 2 TeV

For the pseudo-asimov data injected Z' 3 TeV, Pre-fit and Post-fit $m_{t\bar{t}}$ distributions are showed in Figure 145 and 146.

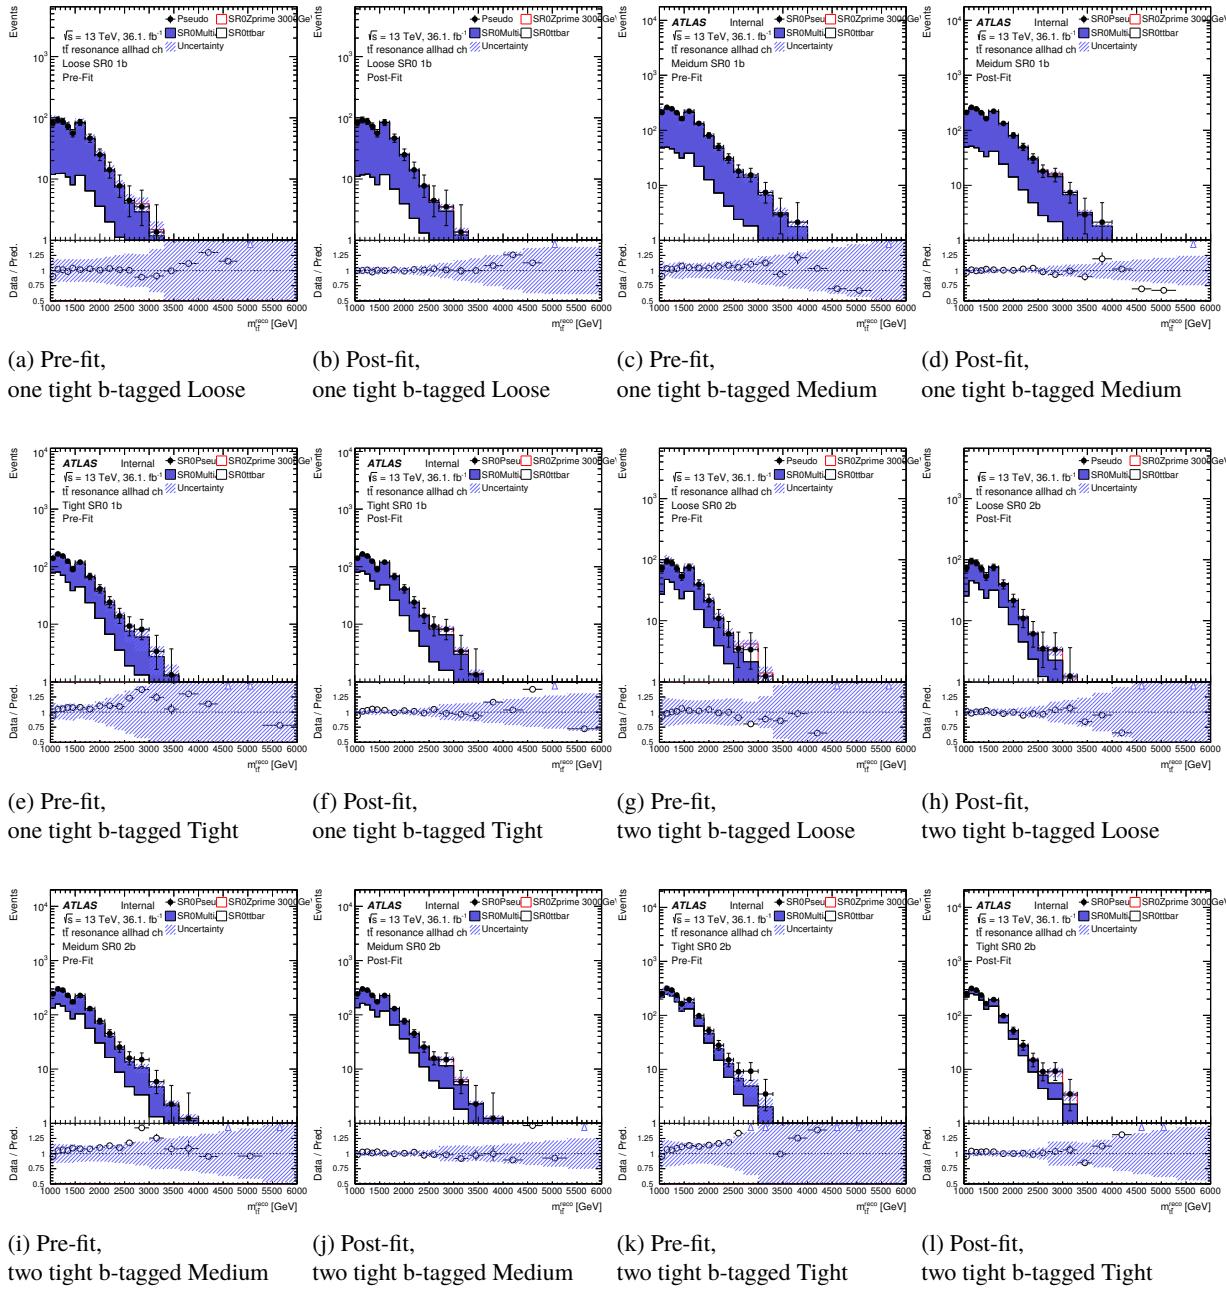

Figure 145: Pre-fit and Post-fit distributions for SR0 and the pseudo date injected Z' 3 TeV

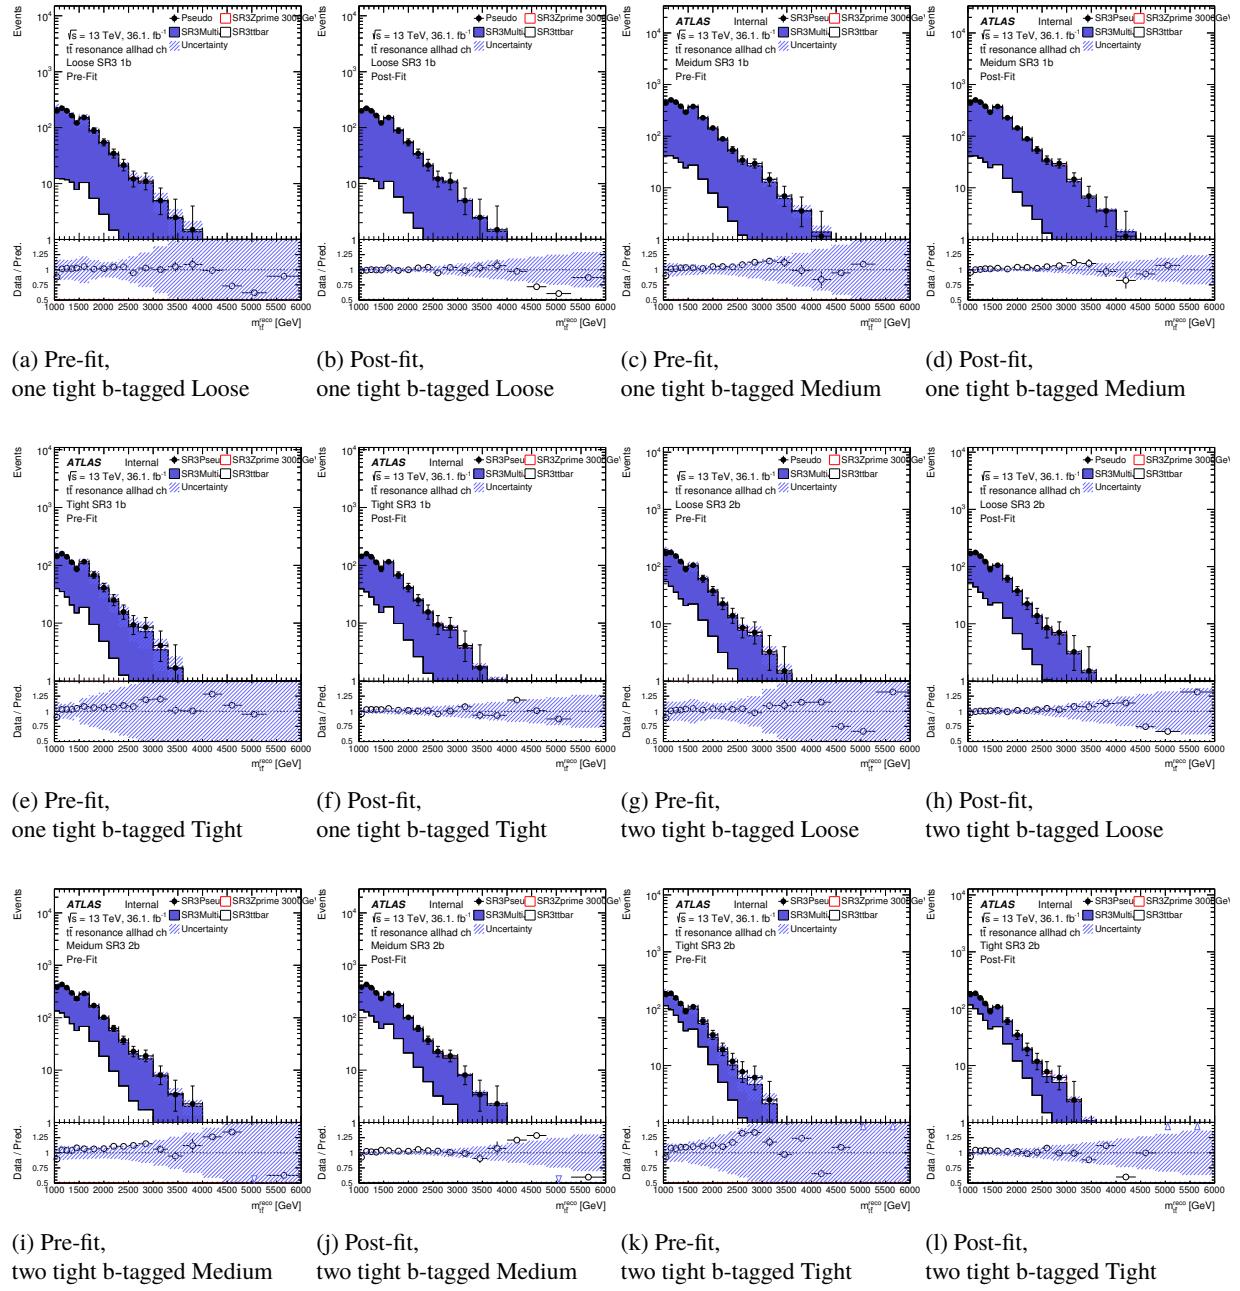

Figure 146: Pre-fit and Post-fit distributions for SR3 and the pseudo date injected Z' 3 TeV

Resulting expected upper limits on production cross section of Z' for the each pseudo-asimov data are shown in Figure 147. The exsistence of signal can be found if Z' signal is included in data as can be seen except for 1 TeV in Figure 147. In low $m_{t\bar{t}}$ region, the buckets analysis has better sensitivity, and the buckets analysis can find such the lower mass signal.

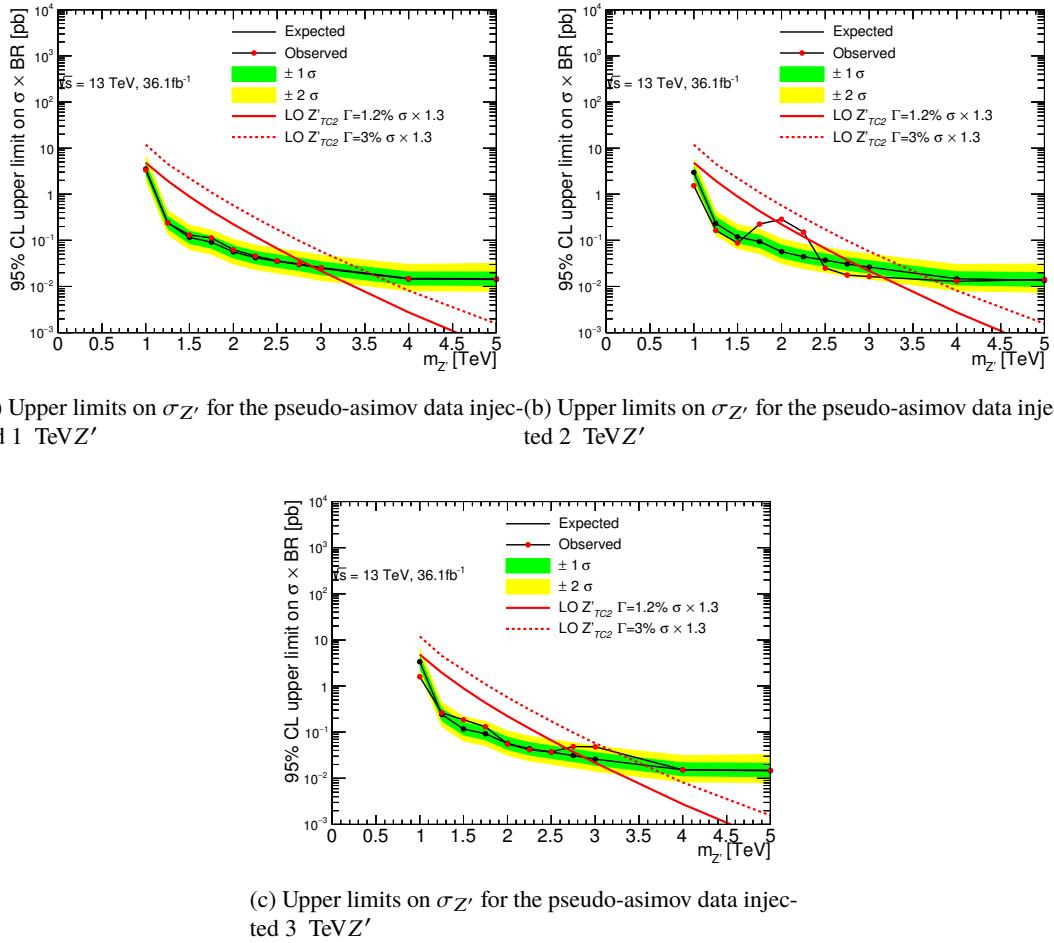

Figure 147: Extracted upper limits on Z' production cross section for the each pseudo-asimov data

D. Other kinematic distributions for each region in τ_{32} -analysis

E. Shape difference of each kinematic distribution for $\tau_{32,wta}$ -likelihood ratio

In order to reduce the effect of statistical uncertainty, $\tau_{32,wta}$ -likelihood categories (loose, medium, tight) are merged. The shape differences of kinematic distribution between each $\tau_{32,wta}$ -likelihood category are small. Those results of shape difference are showed in this appendix.

E.1. MC $t\bar{t}$ shape difference
